Abstract

We study the random composition of a small family of $O(n^3)$ simple permutations on $\{0, 1\}^n$. Specifically we ask how many randomly selected simple permutations need be composed to yield a permutation that is close to $k$-wise independent. We improve on the results of Gowers [12] and Hoory et al. [13] and show that up to a polylogarithmic factor, $n^2k^2$ compositions of random permutations from this family suffice. In addition, our results give an explicit construction of a degree $O(n^3)$ Cayley graph of the alternating group of $2^n$ objects with a spectral gap $\Omega(2^{-n}/n^2)$, which is a substantial improvement over previous constructions.

Keywords: Mixing-time, k-wise independent permutations, cryptography, multicommodity flow, reversible computation.

A naturally occurring question in cryptography is how well the composition of simple permutations drawn from a simple distribution resembles a random permutation. Although such constructions are a common source of security for block ciphers like DES and AES, their mathematical justification (or lack thereof) is troubling.

This motivated the investigation of Hoory et al. [13] who considered the notion of almost $k$-wise independence. Namely, that the distribution obtained when applying a permutation from a given distribution to any $k$ distinct elements is almost indistinguishable from the distribution obtained when applying a truly random permutation. Therefore, the question is how close is the composition of $T$ random simple permutations to $k$-wise independent?

Another motivation is a fundamental open problem in the theory of expanding graphs. \(^1\) Namely, the problem of constructing a constant degree expanding Cayley graph of the symmetric group. A possible relaxation of this problem is to ask whether one can find a small set of simple permutations such that its action on $k$ points yields an expanding graph.

It turns out that these two problems reduce to bounding the mixing time and the spectral gap of the random walk on the same graph. This walk, $P$, is defined on the state space of $k$-tuples of

\(^{1}\)A solution to this problem was announced recently by Kassabov [14].
distinct elements from the \( n \)-dimensional binary cube. In each step it randomly selects a simple permutation and applies it to each of the \( k \) elements at its current position. The mixing time, \( \tau(\epsilon) \), is the number of steps needed to come \( \epsilon \)-close to the uniform distribution (in total variation distance), and the spectral gap, \( \text{gap}(P) \), is the difference between the two largest eigenvalues of \( P \)'s transition matrix.

Following the construction of DES, and previous work by Gowers [12] and Hoory et al [13], we consider the class of width 2 simple permutation, denoted \( \Sigma \). The action of such a permutation on an element of the \( n \)-dimensional binary cube is to XOR a single coordinate with a Boolean function of 2 other coordinates; there are \( 16n(n-1)(n-2) \) such permutations.

These problems were first considered by Gowers [12] who gave a \( \tilde{O}(n^3k(n^2 + k)(n^3 + k)) \) bound on the mixing time, by lower bounding the spectral gap \( 1/\text{gap}(P) = \tilde{O}(n^2(n^2 + k)(n^3 + k)) \). Subsequently, Hoory et al. [13] improved the bound on the mixing time to \( \tilde{O}(n^3k^3) \) by proving that \( 1/\text{gap}(P) = \tilde{O}(n^2k^2) \). Both results were achieved using the canonical paths technique, and neither result applies for \( k > 2^{n/2} \). Using the comparison technique, in conjunction with the theory of reversible computation, we give better bounds for all values of \( k \) up to the largest conceivable value, \( k = 2^n - 2 \).

**Theorem 1.** \( \tau(\epsilon) = \tilde{O}(n^2k^2 \cdot \log(1/\epsilon)) \), as long as \( k \leq 2^{n/50} \).

**Theorem 2.** \( 1/\text{gap}(P) = O(n^2k) \) for all \( k \leq 2^n - 2 \).

Using the well known connection between the mixing time and the spectral gap Theorem 2 implies:

**Corollary 3.** \( \tau(\epsilon) = O(n^2k \cdot (nk + \log(1/\epsilon))) \) for all \( k \leq 2^n - 2 \).

The proofs of both Theorems are based on the comparison technique for Markov chains [8]. To prove Theorem 2 we compare the random walk \( P \) either to a Glauber dynamics Markov chain or to the random walk on the alternating group using 3-cycles. To prove Theorem 1 we observe that after a short preamble the random walk \( P \) is almost surely in a “generic” state. Consequently, it suffices to bound the mixing time of a Markov chain restricted to “generic” states. To this end we again employ the comparison technique, but with a better comparison constant. In all cases we construct the multicommodity flows required by the comparison technique using ideas from the theory of reversible computation.

It follows from [13, 17] that these results apply also in the more general setting of adaptive adversaries (see references for a definition).

**Corollary 4.** Let \( T \) be the minimal number of random compositions of independent and uniformly distributed permutations from \( \Sigma \) needed to generate a permutation which is \( \epsilon \)-close to \( k \)-wise independent against an adaptive adversary. Then \( T = \tilde{O}(n^2k^2 \cdot \log(1/\epsilon)) \) for \( k \leq 2^{n/50} \), and \( T = O(n^2k \cdot (nk + \log(1/\epsilon))) \) for \( k \leq 2^n - 2 \).

### 1 Preliminaries

Let \( f \) be a random permutation on some base set \( X \). Denote by \( X^{(k)} \) the set of all \( k \)-tuples of distinct elements from \( X \). We say that \( f \) is \( \epsilon \)-close to \( k \)-wise independent if for every \( (x_1, \ldots, x_k) \in X^{(k)} \)\(^2\) Notation \( \tilde{O} \) suppresses a polylogarithmic factor in \( n \) and \( k \).
the distribution of \((f(x_1), \ldots, f(x_k))\) is \(\epsilon\)-close to the uniform distribution on \(X^{(k)}\). We measure the distance between two probability distributions \(p, q\) by the total variation distance, defined by
\[
d(p, q) = \frac{1}{2} ||p - q||_1 = \frac{1}{2} \sum_{\omega} |p(\omega) - q(\omega)| = \max_{A} \sum_{\omega \in A} p(\omega) - q(\omega).
\]
Assume a group \(H\) is acting on a set \(X\) and let \(S\) be a subset of \(H\) closed under inversion. Then the Schreier graph \(G = \text{sc}(S, X)\) is defined by \(V(G) = X\) and \(E(G) = \{(x, xs) : x \in X, s \in S\}\). For a sequence \(\omega = (s_1, \ldots, s_\ell) \in S^\ell\) we denote \(x\omega = xs_1 \cdots s_\ell\), and we sometimes refer by \(x\omega\) to the walk \(x, xs_1, \ldots, xs_1 \cdots s_\ell\).

The random walk \(X_0, X_1, \ldots\) associated with a \(d\)-regular graph \(G\) is defined by the transition matrix \(P_{uv} = \Pr[X_{i+1} = u | X_i = v]\) which is \(1/d\) if \((v, u) \in E(G)\) and zero otherwise. The uniform distribution \(\pi\) is stationary for this Markov chain. If \(G\) is connected and not bipartite, we know that given any initial distribution of \(X_0\), the distribution of \(X_t\) tends to the uniform distribution. The mixing time of \(G\) is \(\tau(\epsilon) = \max_{v \in V(G)} \min\{t : d(P^t(v, \cdot), \pi) < \epsilon\}\), where \(P^t(v, \cdot)\) is the probability distribution of \(X_t\) given that \(X_0 = v\). It is not hard to prove (see [3] Lemma 20) that
\[
\tau(2^{-\ell-1}) \leq \ell \cdot \tau(1/4). \tag{1}
\]
Let \(1 = \beta_0 \geq \beta_1 \geq \cdots \geq \beta_{|V(G)|}\) be the eigenvalues of the transition matrix \(P\). We say that this random walk is lazy if for some constant \(\delta > 0\) we have \(P_{vv} \geq \delta\) for all \(v \in V(G)\). We denote the spectral gap \(1 - \beta_1\) of the Markov chain \(P\) by \(\text{gap}(P)\).

Two fundamental results relating the spectral gap of a Markov chain to its mixing time are the following:

**Theorem 5.** ([11] Proposition 3) If the random walk on \(G\) is lazy then \(\tau(\epsilon) = O(\log(|V(G)|/\epsilon) / \text{gap}(P))\).

**Theorem 6.** ([12] Proposition 1.ii] or [11] Chapter 4) For any time reversible Markov chain \(P\) and \(\epsilon > 0\), \(\text{gap}(P) = \Omega(\log(1/2\epsilon) / \tau(\epsilon))\).

### 2 Composing simple permutations

Another building block that we use are results on reversible computation that enables us to compose simple permutations to construct permutations that are easier to work with. A classical result of Coppersmith and Grossman [3] is that for \(n > 3\) the set of width 2 simple permutations generates exactly the alternating group \(A_n\). Thus, all compositions must be even permutations.

Formally, we define the set of width \(w\) simple permutations, \(\Sigma_w\), as the set of permutations \(f_{i,J,h}\) where \(i \in [n]\), \(J = \{j_1, \ldots, j_w\}\) is a size \(w\) ordered subset of \([n]\) \(\setminus \{i\}\), and \(h\) is a Boolean function on \(\{0, 1\}^w\). The permutation \(f_{i,J,h}\) maps \((x_1, \ldots, x_n) \in \{0, 1\}^n\) to \((x_1, \ldots, x_{i-1}, x_i \oplus h(x_{j_1}, \ldots, x_{j_w}), x_{i+1}, \ldots, x_n)\). We are primarily interested in width 2 simple permutations, and denote \(\Sigma = \Sigma_2\).

**Theorem 7.** (Barenco et al. [3]) The permutation that flips the \(n\)-th bit of input \(x\) if and only if the first \(w\) bits of \(x\) are 1 can be implemented as a composition of \(O(w)\) permutations from \(\Sigma\), as long as \(w \leq n - 2\).
To prove that 1 random walk on this graph mixes rapidly.

This follows from the fact that the graph each of the rows. Then Lemma 11. Technique enables one to lower bound gap( 1 ) by gap( 1 )/A, where \( \tilde{P} \) is some other Markov chain, and A is the comparison constant. In our case, all chains are walks on regular graphs. An upper bound on A is obtained by constructing a multicommodity flow on the underlying graph of P. The

\begin{theorem}
(Brody [4]) for any distinct \( x, y, z \in \{0, 1\}^n \), one can compose \( O(n) \) permutations from \( \Sigma \) to obtain the 3-cycle \( (xyz) \).
\end{theorem}

A length \( \ell \) implementation of the permutation \( \sigma \) is a sequence of permutations \( \sigma_1, \ldots, \sigma_\ell \) from \( \Sigma \) whose composition is \( \sigma \). Theorem \( \[8\]\) gives a length \( O(n) \) implementation for 3-cycles. We would like to use this implementation to construct a multicommodity flow with low load on all edges. However, Theorem \( \[8\]\) does not guarantee this. We solve this problem by randomizing the implementation, enabling us to prove a stronger theorem.

A length \( \ell \) randomized implementation of the permutation \( \sigma \) is a sequence of random permutations \( \sigma_1, \ldots, \sigma_\ell \) from \( \Sigma \) whose composition is \( \sigma \). In Theorem \( \[4\] \) we give a randomized implementation for 3-cycles, such that applying any prefix \( \sigma_1 \cdots \sigma_\ell \) of the randomized implementation of a uniformly random 3-cycle \( (xyz) \) to \( x \) yields a string that looks random. Namely, its min-entropy \( H_\infty(\cdot) \) is high, which is the minimum amount of information revealed when exposing the value of a random variable \( X \), that is \( H_\infty(X) = \min \chi(-\log_2(\Pr[X = \chi])) \).

\begin{theorem}
Let \( x, y, z \in \{0, 1\}^n \) be uniformly distributed and distinct. Then there is a length \( L = O(n) \) randomized implementation \( \sigma_1 \cdots \sigma_L \) of the 3-cycle \( (xyz) \) such that for all \( \ell \in [L] \) the min-entropy of \( (x\sigma_1 \cdots \sigma_{\ell-1}, \sigma_\ell) \) (which is a random variable on \( \{0, 1\}^n \times \Sigma \)) is at least \( \log_2(2^n \cdot n^3) - O(1) \).
\end{theorem}

Note, this implies that the min-entropy of the marginals is big, i.e., \( H_\infty(x\sigma_1 \cdots \sigma_{\ell-1}) \geq n - O(1) \) and \( H_\infty(\sigma_\ell) \geq \log_2(n^3) - O(1) \).

\section{Proof of Theorem \[2\]}

In order to prove that the composition of random permutations from \( \Sigma \) approaches \( k \)-wise independence quickly we construct the Schreier graph \( G_{k,n} = sc(\Sigma, X^{(k)}) \), where \( X^{(k)} \) is the set of \( k \)-tuple with \( k \) distinct elements from the base set \( X = \{0, 1\}^n \). It is convenient to think of \( X^{(k)} \) as the set of \( k \) by \( n \) binary matrices with distinct rows. A simple permutation acts on \( X^{(k)} \) by acting on each of the rows. Then \( P \) is the transition matrix of the random walk on \( G_{k,n} \). We prove that the random walk on this graph mixes rapidly.

To prove that \( 1/\text{gap}(P) = O(n^2 k) \), we first observe that \( \text{gap}(P) \) is monotone nonincreasing in \( k \). This follows from the fact that the graph \( G_{k+1,n} \) is a lift of \( G_{k,n} \) and therefore inherits the spectrum of \( G_{k,n} \). To see this, observe that any eigenfunction of \( G_{k,n} \), can be lifted to an eigenfunction on \( G_{k+1,n} \), where the value of the latter on some \( k+1 \) by \( n \) matrix is the value of the former on the matrix obtained by deleting the last row. The eigenvalues of these two eigenfunctions is the same. In light of this observation, it is sufficient to prove the following two lemmas:

\begin{lemma}
\[2\] \[1\] /\text{gap}(P) = O(n^2 \cdot 2^n) \text{ for } k = 2^n - 2.
\end{lemma}

\begin{lemma}
\[2\] \[1\] /\text{gap}(P) = O(n^2 k) \text{ for } k \leq 2^n /3.
\end{lemma}

We obtain the lower bound on the spectral gap of \( P \) using the comparison technique \[8\]. This technique enables one to lower bound \( \text{gap}(P) \) by \( \text{gap}(\tilde{P})/A \), where \( \tilde{P} \) is some other Markov chain, and \( A \) is the comparison constant. In our case, all chains are walks on regular graphs. An upper bound on \( A \) is obtained by constructing a multicommodity flow on the underlying graph of \( P \). The
flow flows a unit between all pairs of endpoints of edges of $\tilde{P}$ such that the flow through each edge of $P$ is small. To prove Lemmas 10 and 11 we compare $P$ to two different Markov chains. We start with the first Lemma.

\textbf{Proof.} (of Lemma 10) For $k = 2^n - 2$, the state space of $P$ comprises all even permutations of $\{0,1\}^n$. Let $\tilde{P}$ be a Markov chain on this state space, where in each step we pick three distinct elements of the cube $x, y, z \in \{0,1\}^n$ and perform the permutation $(xyz)$. It follows from a result of Friedman [11], that $1/\text{gap}(\tilde{P}) = \Theta(2^n)$. Therefore, it is sufficient to prove that the comparison constant of $P$ to $\tilde{P}$ is $O(n^2)$.

To bound the comparison constant $A$, we need to construct a multicommodity flow $f$ in $G_{k,n}$ that flows a unit between every two matrices $M, M'$ such that $\tilde{P}(M, M') > 0$. Since the chains $P$ and $\tilde{P}$ correspond to random walks on regular graphs with degrees $d = \Theta(n^3)$ and $\tilde{d} = \Theta(2^{3n})$ respectively, the formula given in [8, Theorem 2.3] reduces to:

$$A = \left(\frac{d}{\tilde{d}}\right) \cdot \max_{(N,N') \in E(G_{k,n})} \left\{ \sum_{\gamma: (N,N') \in \gamma} f(\gamma) \cdot |\gamma| \right\}. \tag{2}$$

Let $M, M'$ be two matrices such that $\tilde{P}(M, M') > 0$. Then $M'$ can be obtained by applying some 3-cycle $(xyz)$ to $M$. Recall that the randomized implementation given by Theorem 9 induces a probability distribution on the length $L$ sequences of permutations from $\Sigma$ whose composition is $(xyz)$. Such a distribution naturally translates to a distribution on length $L$ paths from $M$ to $M'$. We obtain a unit flow from $M$ to $M'$ by flowing through each such path $\gamma$ an amount equal to its probability. We claim that the multicommodity flow obtained by repeating this process for all $M, M'$ pairs satisfying $\tilde{P}(M, M') > 0$ yields a small comparison constant.

Since $|\gamma| \cdot (d/\tilde{d}) = \Theta(n \cdot |\Sigma|/2^{3n})$ for all paths $\gamma$ with non-zero flow, the problem of bounding the sum in (2) reduces to bounding the total flow through a given edge $e \in E(G_{k,n})$. Let $\gamma = (M_0, \ldots, M_L)$ be a path from $M_0$ to $M_L$, where $M_L$ is obtained from $M_0$ by applying the 3-cycle $(xyz)$. Assume further that $\gamma$ goes through the edge $e$ at the $\ell$-th step, and that $x$ is the $r$-th row of $M$. For any of the $\Theta(2^{3n} \cdot n)$ possible assignments to $x, y, z, \ell, r$, we can determine the distribution of the $r$-th row of the matrices $M_0, \ldots, M_L$. In particular, the probability that $(M_{L-1}, M_L)$ is equal to $e$ is bounded by the probability that they coincide in their $r$-th row. By Theorem 9 in average over all assignments to $x, y, z, \ell, r$, this probability is $O(1/2^n |\Sigma|)$. Putting it all together yields that, up to a constant factor, the comparison constant $A$ is bounded $(n \cdot |\Sigma|/2^{3n}) \cdot (2^{4n} \cdot n) \cdot (1/2^n |\Sigma|) = n^2$, as claimed.

\textbf{Proof.} (of Lemma 11) Let $\tilde{P}$ be the a Markov chain on the same state space as $P$, which is the $k$ by $n$ binary matrices with distinct rows. If the current state of $\tilde{P}$ is the matrix $M$, then the next state is determined by picking a row $r \in \{1, \ldots, k\}$ and setting it to a random new value that is distinct from all other $k - 1$ rows. The process $\tilde{P}$ is the Markov chain of coloring the clique on $k$ vertices with $2^n$ colors defined in [11, section 4.1]. Proposition 4.5 therein bounds its mixing time by $\tilde{\tau}(e) = O(k \log(k/e))$ as long as $k \leq 2^n/3$. Setting $e = 1/4k$ in Theorem 9 implies

3 Altematively, one can define a transition of $\tilde{P}$ as performing two random transpositions (not necessarily disjoint) and use a result of Diaconis and Shahshahani [2] that $1/\text{gap}(\tilde{P}) = \Theta(2^n)$.
that \( \text{gap}(\tilde{P}) = \Omega(1/k) \). Therefore, as in the proof of Lemma \[10\] it is sufficient to prove that the comparison constant of \( P \) to \( \tilde{P} \) is \( O(n^2) \).

Given matrices \( M, M' \) such that \( \tilde{P}(M, M') > 0 \), we know that \( M' \) is obtained from \( M \) by changing the value of some row \( r \) from \( x \) to \( y \). To construct paths from \( M \) to \( M' \), we note that \( M' \) can be obtained by applying the 3-cycle \((xyz)\) to \( M \) for any \( z \in \{0,1\}^n \) that is distinct from all rows of \( M, M' \). We choose \( z \) at random from the \( 2^n - (k+1) \) allowed values. As in the proof of Lemma \[10\] the randomized implementation of \((xyz)\), given by Theorem \[9\], defines a distribution on paths from \( M \) to \( M' \) and therefore a multicommodity flow. We turn to bound the comparison constant, given by \[2\].

As before, \(|\gamma| \cdot (d/\tilde{d}) = \Theta(n \cdot |\Sigma|/k2^n)\) for all \( \gamma \) with non-zero flow, and it suffices to bound the flow through some edge \( e \in E(G_{k,n}) \). We enumerate over the choices of the position \( \ell \), row \( r \) and distinct \( x, y \), which make a total of \( \Theta(nk2^{2n}) \) possible values. Again we apply Theorem \[9\] to argue that in average, the probability of agreement with \( e \) is bounded by \( O(1/|\Sigma|2^n) \). \( \text{4} \) Therefore, up to a constant factor, \( A = (n \cdot |\Sigma|/k2^n) \cdot (nk2^{2n}) \cdot (1/|\Sigma|2^n) = n^2 \), as claimed. \( \square \)

4 Proof of Theorem \[11\]

In light of inequality \[11\], it is sufficient to prove that \( \tau(1/4) = \tilde{O}(n^2k^2) \). The outline of the proof is the following. We start by introducing the notion of a generic matrix, and as suggested by the name, most matrices are generic. The proof then proceeds by arguing that after a short random walk almost surely all matrices encountered are generic. Therefore, it is sufficient to bound the mixing time of a walk that is restricted to generic matrices. For such a walk, we can compare the chain to a chain defined only on generic matrices and achieve a much smaller comparison constant. This yields the desired bound, \( \tilde{O}(n^2k^2) \).

Let \( w = 10 \cdot (\log k + \log n) \). By assumption, we have \( w \leq n/4 \) for a sufficiently large \( n \), and we set \( p = \lceil n/2w \rceil \). Let \( C_1, \ldots, C_p, C \) be a partition of \( [n] \) such that \( |C_i| = w \) for \( i = 1, \ldots, p \) and \( |C| = n - pw \). Consequently, \( n/4 \leq n/2 - w < |C| \leq n/2 \).

We say that a \( k \) by \( n \) matrix is generic, if for all \( j \in [p] \), its restriction to \( C_j \) has distinct rows. It is not difficult to check that a uniformly distributed matrix \( M \) is almost surely generic. In fact, it is sufficient that the rows of \( M \) are \( 2^{-w} \)-close to 2-wise independent, since then the probability that \( M \) is not generic is bounded by \( p \) times the probability that the restriction of \( M \) to \( C_j \) doesn’t have distinct rows. This yields the bound \( p \cdot \binom{k}{2} \cdot (2 \cdot 2^{-w}) = o(1/n^3k^3) \) and implies the following lemma:

**Lemma 12.** If the rows of a random \( k \) by \( n \) matrix \( M \) are \( 2^{-w} \)-close to 2-wise independent, then \( M \) is generic with probability \( 1 - o(1/n^3k^3) \).

It follows from a result of Chung and Graham about the mixing time of the “Aldous Cube” \[5\], that the number of steps needed to come close to 2-wise independence, which is the same as the mixing time of \( G_{2,n} \), is \( O(n \log n) \). This is stated in the following lemma (whose proof is deferred to Section \[6\])

\[4\]One should note that \( z \) is uniformly distributed only over \( 2^n - (k+1) > 2^{n-1} \) values. However, this is equivalent to conditioning a uniform \( z \) on an event with probability at least half and therefore (by Lemma \[10\]) can only increase the probability of agreement with \( e \) by a factor of two.

6
Lemma 13. For all $w \geq 1$ the $\epsilon$ mixing time of the Schreier graph $sc(\Sigma_w, X^{(2)})$ is $O(n \log n \log(1/\epsilon))$. 

Therefore, the matrix obtained after $T_1 = O(n \log n \cdot w) = O(n \log n \cdot (\log k + \log n))$ steps is $2^{-w}$-close to 2-wise independent, and by Lemma 12 it is generic with probability $1 - o(1/n^3k^3)$. This implies that if we proceed by $T_2 = O(n^3k^3)$ steps, then all $T_2$ matrices encountered are generic with probability $1 - o(T_2/n^3k^3) > 1 - \epsilon_1$, for any fixed $\epsilon_1 > 0$ and sufficiently large $n$.

We introduce a new Markov chain $P'$. The state space of $P'$ consists of all generic $k$ by $n$ matrices. If the chain is currently at the matrix $M$, then the next state is determined as follows. We pick a uniformly distributed simple permutation $\sigma \in \Sigma$. If $M\sigma$ is generic, we move to $M\sigma$. Otherwise, we remain at $M$. Let $\tau'(\epsilon)$ denote the $\epsilon$-mixing time of $P'$, and require that $T_2 \geq \tau'(\epsilon_2)$ for some fixed $\epsilon_2 > 0$.

We claim that as long as $2\epsilon_1 + \epsilon_2 < 1/4$ the mixing time of $P$ can be bounded by $\tau(1/4) \leq T_1 + T_2$. To see this, let $M$ be some $k$ by $n$ matrix with distinct rows, and consider following two matrices. The first matrix $M'$ obtained when starting at $M$ and walking $T_1 + T_2$ steps using $P$. The second matrix $M''$ is defined as follows. Let $\hat{M}$ be the matrix obtained when starting at $M$ and performing $T_1$ steps of $P$. If $\hat{M}$ is not generic, we set $M'' = \hat{M}$. Otherwise, $M''$ is the matrix reached by the length $T_2$ walk using $P'$ that starts at $\hat{M}$. We claim that $d(M', M'') \leq \epsilon_1$ and that $M''$ is $(\epsilon_1 + \epsilon_2)$-close to the uniform distribution over $k$ by $n$ matrices with distinct rows. Proving those claims will imply that

$$\tau(1/4) \leq \tau'(\epsilon_2) + O(n \log n \cdot (\log k + \log n)), \quad (3)$$

as long as $\tau'(\epsilon_2) = O(n^3k^3)$.

We start by checking that indeed $d(M', M'') \leq \epsilon_1$. It is convenient to think of the two length $T_1 + T_2$ walks from $M$ to $M'$ and $M''$ as defined over the same probability space $\Sigma^{T_1 + T_2}$ which is the choice of a simple permutation in each of the $T_1 + T_2$ steps. Denote the the $P$-walk by $(M_0 = M, M_1, \ldots, M_{T_1 + T_2} = M')$. Then, if all the matrices $M_{T_1}, \ldots, M_{T_1 + T_2}$ are generic, it coincides with the walk leading to $M''$, and in particular we have $M' = M''$. By the previous arguments, this event happens at least with probability $1 - \epsilon_1$, implying that $d(M', M'') \leq \epsilon_1$.

The proof that $M''$ is $(\epsilon_1 + \epsilon_2)$-close to uniform is more delicate. We know that the matrix $\hat{M}$ is generic with probability at least $1 - \epsilon_1$. Also, since $T_2 \geq \tau'(\epsilon_2)$, we know that conditioned on $\hat{M}$ being generic, $M''$ is $\epsilon_2$-close to the uniform distribution. Therefore $M''$ is $(\epsilon_1 + \epsilon_2)$-close to the uniform distribution over matrices with distinct rows. This argument can be easily formalized using Lemma 13 of Section 6.

We are left with the proof of the following lemma.

Lemma 14. $\tau'(1/4) = \tilde{O}(n^2k^2)$.

To bound the mixing time of the Markov chain $P'$, we apply the comparison technique [4]. We compare $P'$ to the Markov chain $\hat{P}$ defined on the same state space, the $k$ by $n$ generic matrices. Given that $\hat{P}$ is at a matrix $M$, we determine the next state as follows. With probability half we pick a random column $c \in C$ and row $r \in [k]$ and flip the corresponding bit with probability half.

\footnote{Note that by our assumptions, the distance between the uniform distribution over matrices with distinct rows and generic matrices is $o(1)$}
Otherwise, we pick at random an index \(i \in [p]\), a row \(r \in [k]\) and a string \(\alpha \in \{0, 1\}^w\) that is distinct from all other \(k - 1\) rows in the restriction of \(M\) to the columns \(C_i\). We set the bits at row \(r\) and columns \(C_i\) to \(\alpha\).

Consequently, the following two lemmas, imply Lemma 14. Note that we need not worry about the smallest eigenvalue of \(P'\) since a random permutation from \(\Sigma\) is the identity with probability \(1/16\).

**Lemma 15.** \(\text{gap}(\tilde{P}) = \Omega(1/nk)\).

**Lemma 16.** The comparison constant \(A\) of \(\tilde{P}\) to \(P'\) satisfies \(A = \tilde{O}(1)\).

**Proof.** (of Lemma 15)

Consider two Markov chains \(\tilde{P}_1\) and \(\tilde{P}_2\):

1. The state space of \(\tilde{P}_1\) are the \(k\) by \(w\) binary matrices with distinct rows. At each step one chooses a random row and sets it to a random new value distinct from all other \(k - 1\) rows. This chain is exactly the coloring chain of a clique on \(k\) vertices with \(2^w\) colors of [14, Proposition 4.5], and as in the proof of Lemma 11, it satisfies \(\text{gap}(\tilde{P}_1) = \Omega(1/k)\).

2. \(\tilde{P}_2\) is the random walk on the \((n - wp) \cdot k\) dimensional binary cube, where in each step with probability half, one flips a random coordinate. Therefore, \(\text{gap}(\tilde{P}_2) = \Omega(1/nk)\).

One can think of the chain \(\tilde{P}\) as the product of \(p\) copies of \(\tilde{P}_1\) and one copy of \(\tilde{P}_2\). Indeed the state space of \(\tilde{P}\) is the direct product of the \(p + 1\) state spaces. Moreover, a step of \(\tilde{P}\) performs a move of \(\tilde{P}_2\) with probability \(1/2\) and otherwise performs the move in a randomly selected copy of \(\tilde{P}_1\). It is straightforward to check that the spectral gap of \(\tilde{P}\) is \(\min(\text{gap}(\tilde{P}_1)/p, \text{gap}(\tilde{P}_2))/2\), implying the desired bound.

**Proof.** (of Lemma 16)

Let \(G'\) be the underlying graph of \(P'\). The vertices of \(G'\) are the generic \(k\) by \(n\) matrices, and \((N, N')\) is an edge of \(G'\) if \(P'(N, N') > 0\). To bound the comparison constant \(A\), we need to construct a multicommodity flow \(f\) in \(G'\) that flows a unit between every two matrices \(M, M'\) such that \(\tilde{P}(M, M') > 0\). The chains \(P'\) and \(\tilde{P}\) correspond to random walks on regular graphs with degrees \(d' = \Theta(n^3)\), \(\tilde{d} = \Theta(kn2^w/w)\) respectively, and as before the comparison constant \(A\) is defined by \([2]\).

To build a path \(\gamma\) from \(M\) to \(M'\) we need to distinguish two types of \(\tilde{P}\) transitions. Type (i) flips the bit at row \(r\) and column \(c \in C\). Type (ii) changes the bits at row \(r\) and columns \(C_i\) from \(\alpha\) to \(\alpha'\). We start by constructing the type (i) paths.

Let \(j \in [p]\) be a random index, and let \(\beta \in \{0, 1\}^w\) be the restriction of the \(r\)-th row of \(M\) to \(C_j\). Also let \(S\) be a random sequence of \(w - 1\) distinct elements from \(C \setminus \{c\}\). The unit flow from \(M\) to \(M'\) is along paths \(\gamma = \gamma_{M, M'}^{S, j}\). Each such path is defined by composing simple permutations from \(\Sigma\) to achieve the permutation that acts on \(x \in \{0, 1\}^n\) by flipping coordinate \(c\) if the restriction of \(x\) to \(C_j\) is \(\beta\). Clearly such a permutation maps \(M\) to \(M'\). We follow the method of Barenco et al. [3] to build an AND gate with \(w\) inputs. This gate inverts its output bit (the coordinate \(c\)) if
its $w$ inputs (the coordinates $C_j$) have some fixed value $\beta$. The coordinates in the set $S$ are used as “scratch”.

Let $C_j = \{j_1, \ldots, j_w\}$, $S = \{s_1, \ldots, s_{w-1}\}$ and $\beta = (b_1, \ldots, b_w)$. Let $\sigma_1$ be the simple permutation that flips coordinate $s_1$ of $x \in \{0,1\}^n$ if $x_{j_1}$ is equal to $b_1$, and let $\sigma_\ell$ for $2 \leq \ell \leq w-1$ be the simple permutation that flips coordinate $s_\ell$ if $x_{s_{\ell-1}}$ is one and $x_{j_\ell}$ is equal to $b_\ell$. Also, we denote by $\tau_i$ the simple permutation that flips $x_c$ if $x_{s_{w-1}}$ is one and $x_{j_w}$ is equal to $b_w$. We claim that the following permutation flips coordinate $c$ of $x \in \{0,1\}^n$ if the restriction of $x$ to $C_j$ is equal to $\beta$:

$$\sigma = (\tau_c \sigma_{w-1} \cdots \sigma_2 \sigma_1 \sigma_2 \cdots \sigma_{w-1})^2$$

To see this, one checks by induction that $\sigma_\ell \cdots \sigma_1 \sigma_\ell$ flips coordinate $s_\ell$ if $x_{j_1}, \ldots, x_{j_\ell}$ is equal to $b_1, \ldots, b_\ell$.

For the type (ii) paths, we need to change the bits at row $r$ and columns $C_i$ from $\alpha$ to $\alpha'$. The problem is that if we change $\alpha$ to $\alpha'$ bit by bit, as suggested by the construction of type (i) paths, we might violate row distinctness. To solve this problem, we start our path by applying a length $L = O(w \log w \cdot (1 + 2 \log k))$ sequence $\phi$ of simple permutations with indices restricted to $C_i$. Let $M = M \phi$ and $M' = M' \phi$, and let $C_i'$ and $C_i''$ be the first and last $\lfloor (w - 1)/2 \rfloor$ columns of $C_i$. We say that $\phi$ is valid if for both the restriction of $M$ to $C_i''$ and for the restriction of $M'$ to $C_i'$, have distinct rows. By Lemma 13 we know for a random $\phi$, both $M$ and $M'$ are $1/8k^2$-close to 2-wise independence. Therefore, a random $\phi$ is not valid with probability bounded by $k^2 \cdot (2^{-w/2+1} + 1/8k^2) \leq 1/4$. If $\phi$ is valid we define a path $\gamma = \gamma_{M, M'}$ from $M$ to $M'$, where $j \in [p] \setminus \{i\}$ and $S$ is a length $w - 1$ sequence of elements from $C$. The path is prefixed by $\phi$ to get from $M$ to $M$ and is suffixed by $\phi^{-1}$ to get from $M'$ to $M'$. Let $\hat{\alpha}$ and $\alpha'$ be the restriction of the $r$-th row of $M$ and $M'$ to $C_i$ respectively, and let $\beta$ be the restriction of the $r$-th row of $M$ to $C_j$.

Then the middle path connecting $M$ to $M'$ is defined as follows:

$$\sigma = [(\prod_{c \in C_i' \setminus \{\hat{a}_c \neq \alpha'_c\}} \tau_c) \cdot \sigma_{w-1} \cdots \sigma_2 \sigma_1 \sigma_2 \cdots \sigma_{w-1}]^2 \cdot ([\prod_{c \in C_i \setminus \{\hat{a}_c \neq \alpha'_c\}} \tau_c) \cdot \sigma_{w-1} \cdots \sigma_2 \sigma_1 \sigma_2 \cdots \sigma_{w-1}]^2,$$

where $\tau_c$ and $\sigma_\ell$ are as defined for the type (i) sequences. Therefore it is guaranteed that the matrices encountered along the first and second half of the sequence agree with $\hat{M}$ on the columns $C_i''$ and with $\hat{M}'$ on the columns $C_i'$ respectively. Since $\phi$ is valid, this implies that we never attempt to move to a non-generic matrix throughout the entire path. We define the unit flow from $M$ to $M'$ by splitting the flow uniformly between all valid paths $\gamma$ designated by $S, j, \phi$.

There are two points that need special attention in the constructed type (i) and type (ii) paths. The first point is that all indices of the simple permutations used in $\phi$ are in $C_i$. This is unacceptable for us, as it induces an undue load on a small subset of $\Sigma$. To solve this problem we replace each simple permutation used in $\phi$ by a constant length sequence that avoids that problem. For example, the permutation that flips coordinate $i_1$ if $i_2$ and $i_3$ are 1, denoted $\chi_{i_1,i_2,i_3}$, is replaced by the sequence $(\chi_{s_2,s_1,i_3} \chi_{s_1,i_2}, \chi_{s_2,s_1,i_3}, \chi_{i_1,s_2})^2$ where permutation $\chi_{i_1,i_2}$ XORs coordinate $i_1$ with $i_2$.

The second point is that some of the simple permutations used ($\sigma_1$ and some of the permutations in $\phi$) do not use three indices. However, in the definition of $\Sigma$, we have three indices at our disposal even if we don’t use all three. We use this to guarantee that all simple permutations used have one index in $C_j$ and two from $S$ or $c$ for type (i) paths or $C_i$ for type (ii) paths.
To complete the proof, we have to bound the comparison constant $A$ given by (2). We have $d'/\tilde{d} = \Theta(n^2w/k2^w)$ and $|\gamma| = O(L)$. Also, $f(\gamma)$ is $\Theta(w/n(m)_{w-1})$ for type (i) paths and $\Theta(w/|\Sigma|^L n(m)_{w-1})$ for type (ii) paths, where we denote $m = |C|$, $(m)_{q} = m(m-1)(m-2)\cdots(m-q+1)$, and $|\Sigma|^L$ as the width $2$ simple permutations restricted to the $w$-dimensional cube. Therefore, we only have to bound the maximal number of $\gamma^{S,j}_{M,M'}$ and $\gamma^{S,j,\phi}_{M,M'}$ paths through an edge $(N,N')$.

We start with type (i) paths. The first step is to extract as much information as possible about a path $\gamma$ through $(N,N')$ by considering the simple permutation $s$ associated with $(N,N')$. Note first that $s$ determines $j$. Moreover, since only one of $\sigma_1,\ldots,\sigma_{w-1}$ and $\tau_e$ can be equal to $s$, any path $\gamma$ using $s$, must use it in one of $O(1)$ possible positions. Since a permutation $\sigma_i$ for $\ell \in [w-1]$ or $\tau_e$ determines two indices of $S,c$ there are only $\Theta((m)_{w-2})$ choices for $S,c$ that are consistent with $s$. The last thing still needed to reconstruct $\gamma$ is the string $\beta \in \{0,1\}^w$. Since the columns $C_j$ are not modified throughout the entire sequence, $\beta$ must be the restriction of some row of $N$ to $C_j$, limiting $\beta$ to one of $k$ possible values. Therefore, the total number of type (i) paths through $(N,N')$ is $O(k \cdot (m)_{w-2})$, and the contribution of the type (i) sequences to $A$ is:

$$A_{(i)} = O((n^2w/k2^w) \cdot (Lw/(m)_{w}) \cdot (k \cdot (m)_{w-2}) ) = O(Lw^2/2^w) = o(1).$$

For type (ii) paths we distinguish the cases where $(N,N')$ is in the first middle or last sections of a path $\gamma^{S,j,\phi}_{M,M'}$. Consider the first section (and similarly the last). We enumerate over possible positions $\ell \in [L]$. Then we know two indices of the sequence $S$ and one of the $3L$ indices in $C_i$ that where used by $\phi$. Therefore, we have $L \cdot (m)_{w-2} \cdot |\Sigma|^L/|\Sigma|^w$ possible values for $S,i,\phi$ and the position. This enables us to determine $M$ and $M$. We still have to determine the row $r$, the two strings $\alpha,\alpha'$ and the index $j$ which have $O(kn2^w/w)$ possibilities. Therefore the contribution of the first and last sections of type (ii) paths is:

$$A_{(ii,\text{first, last})} = O((n^2w/k2^w) \cdot (Lw/|\Sigma|^w) \cdot (k \cdot (m)_{w-2} \cdot |\Sigma|^L/w2^w) ) = O(L^2) = O((w^2 \log^2 w \cdot (1 + \log k)^2).$$

For the middle section of type (ii) paths, as for the type (i) argument, given $(N,N')$ we first determine the position up to $O(1)$ possible choices. Then we determine the index $i$ or $j$ and two indices from $S$, then we have $O((m)_{w-2} \cdot |\Sigma|^L/w)$ possibilities for $i,j,S,\phi$. Also we have $k2^w$ choices for the row and the strings $\beta,\alpha$ and $\alpha'$. Therefore,

$$A_{(ii,\text{middle})} = O((n^2w/k2^w) \cdot (Lw/|\Sigma|^L(m)_{w}) \cdot (k2^w \cdot (m)_{w-2} \cdot |\Sigma|^L/w) ) = O(Lw).$$

5 Proof of Theorem 9

First, we describe the randomized implementation of a 3-cycle $(xyz)$ using the simple permutations in $\Sigma$. Second, we show that this randomized implementation satisfies the statement of the theorem.
The randomness is introduced into the implementation of \((xyz)\) by using a permutation \(\phi \in S_n\) and two vectors \(v_4, v_5\).

Let \(\phi\) be some permutation of the \(n\) coordinates. If \(\omega = \sigma_1 \cdots \sigma_L\) implements \((x\phi, y\phi, z\phi)\), then \(\omega^\phi\) is an implementation of \((xyz)\), where \(\omega^\phi = \phi \omega \phi^{-1}\) is the conjugation of \(\omega\) with \(\phi\), i.e. the conjugation each of the permutations \(\sigma_i\) used in \(\omega\). Note that the set \(\Sigma\) of simple permutations is closed under conjugation by permutations from \(S_n\), because this just relabels the indices.

For a vector \(v \in \{0,1\}^n\), we denote the first \(n-2\) bits of \(v\) by \(v' \in \{0,1\}^{n-2}\) and the last two bits of \(v\) by \(v'' \in \{0,1\}^2\), i.e., \(v = v' v''\). We call the last two bits the control bits. For convenience, the notation \(v'00, v'01, v'10,\) and \(v'11\) denotes bit vectors comprising the first \(n-2\) bits of \(v\) and the control bits 00, 01, 10, and 11, respectively. Let \((v)_j\) denote the \(j\)-th bit of a vector \(v\). Finally, let \(v_1 = x\phi, v_2 = y\phi\) and \(v_3 = z\phi\).

If \(v'_1\) is equal to \(v'_2\) or to \(v'_3\) then we say that \(\phi\) is invalid. This can only occur if \(x, y,\) or \(z\) are less than Hamming distance 3 apart and \(\phi\) maps all indices on which \(x\) and \(y\) (or \(z\)) differ to the control indices. For the rest of the description we assume that \(\phi\) is valid. Let \(v_4, v_5 \in \{0,1\}^n\) be two additional vectors satisfying the validity requirement of being at least Hamming distance 3 from each other and from the former three vectors.

Observe that \((v_1, v_2, v_3) = \psi_1 \psi_2\) where \(\psi_1 = (v_1, v_2)(v_4, v_5)\) and \(\psi_2 = (v_1, v_3)(v_4, v_5)\). Therefore it suffices to implement the two double transpositions \(\psi_1\) and \(\psi_2\). These are implemented in an identical manner. Each implementation is divided into 15 blocks: a core block, which implements the permutation \(\rho_{core} = (v'_00, v'_01)(v'_510, v'_511)\), and seven block pairs conjugating it.

The first four of these blocks, called \(\pi\)-blocks ensure that the control bits of each of the four vectors are distinct. Specifically, \(v'_i v''_i\) is mapped to \(v'_i c_i\), where \(c_1 = 00, c_2 = 01, c_3 = 10\) and \(c_4 = 11\). If \(v''_i = c_i\) then the corresponding block, labeled \(\pi_i\) performs a nop. Otherwise, block \(\pi_i\) performs the permutation \((v'_i v''_i, v'_i c_i) (v'_i a_i, v'_i b_i)\) where \(\{a_i, b_i\} = \{0,1\}^2 \setminus \{v''_i, c_i\}\).

The remaining three blocks, called \(\tau\)-blocks, map \(v'_1, v'_2\) (or \(v'_3\)), and \(v'_4\) to \(v'_5\), using the control bits to distinguish between the four vectors. Block \(\tau_i\) performs the permutation \(\tau_i = \prod_{v'' \in \{0,1\}^2} (v'_i c_i, v'_i a_i)\), where \(u' = v' \oplus v'_i \oplus v'_5\). Since it can easily be checked that \(\tau_i = \tau_i^{-1}\), that \(\pi_i = \pi_i^{-1}\), and that

\[
\pi_1 \pi_2 \pi_4 \pi_5 \tau_1 \tau_2 \tau_4 \rho_{core} \tau_4 \tau_7 \pi_3 \pi_4 \pi_5 \pi_2 \pi_1 = \psi_1 \quad \text{and} \quad \pi_1 \pi_2 \pi_4 \pi_5 \tau_1 \tau_3 \tau_4 \rho_{core} \tau_4 \tau_3 \tau_1 \pi_5 \pi_4 \pi_3 \pi_1 = \psi_2,
\]

we need only describe the implementation of each of these blocks.

Each of the blocks is implemented using \(O(n)\) simple permutations. Each \(\tau\)-block is implemented by concatenating \(n-2\) simple permutations, where for \(j = 1 \cdots n-2\), the \(j\)-th simple permutation is the identity if \((v'_i)_j = (v'_i)_j\), and otherwise flips the \(j\)-th bit of vector \(v\) if \(v''_i = c_i\).

The implementation of the \(\rho_{core}\) and \(\pi\) blocks is more involved. Permutation \(\rho_{core}\) flips bit \((v'')_2\) if and only if \(v' = v'_5\). Barenco et al. showed how such permutations can be implemented using \(O(n)\) simple permutations, comprising four sub-blocks: \(\rho_{top} \rho_{bot}\rho_{top} \rho_{bot}\) where permutation \(\rho_{top}\) flips bit \((v'')_1\) if the first \([(n-2)/2]\) bits of \(v'\) match the first \([(n-2)/2]\) bits of \(v'_5\), and where permutation \(\rho_{bot}\) flips bit \((v'')_2\) if the latter \([(n-2)/2]\) bits of \(v'\) match the latter \([(n-2)/2]\) bits of \(v'_5\) and \((v'')_1 = 1\). Each sub-block uses the remaining \([(n-2)/2]\) bits as “scratch”, returning them to their original state by the end of the sub-block. For details about the construction of the two sub-blocks see or Lemma.

Each block \(\pi_i\) is implemented in a similar manner using two permutations that are nearly identical.
to the implementation of $\rho_{\text{core}}$. The first (second) permutation performs the identity if $(v')_1 = (c)_1$ (respectively, $(v')_2 = (c)_2$) and otherwise flips bit $(v')_1$ (respectively, $(v')_2$) if $v' = v'_i$.

The length of the implementations of $\psi_1$ and $\psi_2$ is $O(n)$, since each of the seven blocks can be implemented using $O(n)$ simple permutations from $\Sigma$. The randomize implementation of $(xyz)$ is obtained by uniformly choosing at random a valid permutation $\phi$ and the two valid random vectors $v_4, v_5$.

We now prove that this randomized implementation satisfies the statement of the theorem. Let $\Omega = \{x, y, z, v_4, v_5, \phi\}$ be the probability space obtained by uniformly choosing three distinct vectors $x$, $y$, and $z$, and then uniformly choosing a corresponding implementation, which is fixed by $v_4$, $v_5$, and $\phi$. Each point $\omega = (x, y, z, v_4, v_5, \phi) \in \Omega$ corresponds to an implementation $\sigma_1 \cdots \sigma_5$ of the 3-cycle $(xyz)$. The size of $\Omega$ is $\Theta(2^{5n}n!)$, and although not uniform, the probability of each point in $\Omega$ is $O(1/2^{5n}n!)$. Thus, our problem of upper-bounding $\Pr[x_1 \sigma_2 \cdots \sigma_5 = \tilde{x}, \sigma_5 = \tilde{\sigma}]$ reduces to a counting problem.

For all implementations $\omega \in \Omega$, the indices of the $\ell$-th permutation $\sigma_\ell$ depend only on its position, $\ell$, and $\phi$. Moreover, as we change $\phi$ the indices of the $\ell$-th permutation of the implementation of $(x, y, z, v_4, v_5, \phi)$ agree with the indices of some fixed permutation $\tilde{\sigma}$ only on a subset of $S_n$ that is of size $O(n!/n^3)$ and depends only on $\ell$ and $\tilde{\sigma}$.

To establish the theorem we need to prove that for any given $\phi$ the number of choices of $x$, $y$, $z$, $v_4$, and $v_5$, such that $x_1 \sigma_2 \cdots \sigma_5 = \tilde{x}$, is $O(2^{4n})$, implying the number of points in $\Omega$ that agree with $\tilde{x}$ and $\tilde{\sigma}$ is $O(2^{4n}n!/n^3) = O(|\Omega|/2^{4n}n^3)$. This is accomplished by the following lemma:

**Lemma 17.** Let $\phi \in S_n$ be fixed. Then the set of all $x, y, z, v_4, v_5$ such that implementation corresponding to $(x, y, z, v_4, v_5, \phi)$ satisfies the equality $x_1 \sigma_2 \cdots \sigma_5 = \tilde{x}$ is of size $O(2^{4n})$.

**Proof.** (of Lemma 17)

Let $v_1 = x\phi$, $v_2 = y\phi$, $v_3 = z\phi$, and $\tilde{\phi} = \tilde{x}\phi$. Let $\Omega_{\tilde{\phi}, \ell}$ be the set of tuples $(v_1, \ldots, v_5)$ for which $x_1 \sigma_2 \cdots \sigma_5 = \tilde{x}$ is satisfied. Note that this set is independent of $\phi$. Then the claim is that $|\Omega_{\tilde{\phi}, \ell}| = O(2^{4n})$.

The proof is via case analysis with respect to position $\ell$. Without loss of generality we assume that the position is in the first half of the implementation, that which realizes permutation $(v_1, v_2)(v_4, v_5)$, otherwise, swapping $v_2$ and $v_3$ allows the same argument to be reused for the latter half of the implementation. Furthermore, due to symmetry, we assume that the position of $\ell$ is in or to the left of block $\rho_{\text{core}}$. There are four main cases: either $\ell$ is on a boundary between two blocks, $\ell$ is in block $\rho_{\text{core}}$, or $\ell$ is in block $\pi_i$.

![Figure 1: The evolution of $v_1$.](image_url)

In the first case, the position, $\ell$, is on a boundary block. Since each $\pi$-block only toggles bits $(v')_1$ and $(v')_2$, if position $\ell$ is adjacent to a $\pi$-block, then $v' = v'_i$. Thus, all but two bits of $v_1$ are fixed by $\tilde{\phi}$. If position, $\ell$, is on a boundary but is not adjacent to a $\pi$-block, then it must occur after
block $\tau_1$. Since block $\tau_1$ maps $v'_100$ to $v'_100$, and none of the remaining blocks, $\tau_i$ or $\rho_{core}$, change the $v'$ component to any other value, we have $\tilde v' = v'_3$. Thus, all but two bits of $v_5$ are fixed by $\tilde v$, implying that $|\Omega_{\tilde v, \ell}| = O(2^{4n})$.

In the second case, the position, $\ell$, is inside block $\tau_1$. If $i \neq 1$, then none of the simple permutations in block $\tau_1$ flips a bit. Therefore, the value of $\tilde v' = v'_3$; thus fixing all but two bits of $v_5$, as before. If $i = 1$, then at position $\ell$, we know exactly how many of the $n - 2$ simple permutations have already been performed. Let $j$ be this number. Hence we know that $\tilde v' = (v'_5)_1, \ldots, (v'_5)_j, (v'_1)_{j+1}, \ldots, (v'_1)_{n-2}$. Therefore, $j$ bits of $v_5$ and $n - 2 - j$ bits of $v_1$ are therefore fixed by $\tilde v$, implying that $|\Omega_{\tilde v, \ell}| = O(2^{4n})$ as well.

In the third case, the position, $\ell$, is inside block $\rho_{core}$. In this case we must look at the sub-blocks of the block $\rho_{core}$. If the position occurs on a sub-block boundary, and since each of the sub-blocks simply toggles the bits $(v'')_1$ and $(v'')_2$, the remaining bits of $v'_5$ are fixed by $\tilde v'$. If the position $\ell$ is inside a sub-block, then things are only slightly more complicated. Assume that position $\ell$ is in a $\rho_{top}$ sub-block (similar arguments hold for $\rho_{bot}$). Then, $\rho_{top}$ toggles bit $(v'')_1$ if the first half of $v'$ matches the first half of $v'_5$. The bits being matched are never modified and the other half of the bits of $v'$ are used as “scratch”. We know that the first half of $v'$ and $v'_5$ coincide throughout the block $\rho_{top}$, and therefore $\tilde v'$ determines this half of $v'_5$. The operations on the “scratch” half depends only on the fixed half and the position, and therefore can be reversed, reducing the problem to the position occurring at the beginning of $\rho_{top}$. Thus, $\tilde v$ fixes all but two of the bits of $v_5$.

In the last case, the position, $\ell$, is inside a $\pi$-block. Block $\pi_i$ comprises two blocks that are similar to $\rho_{core}$. Each of the two blocks is either the identity or toggles $(v'')_1$ or $(v'')_2$ if $v' = v'_4$. If $i = 1$ then the two blocks in Block $\pi_i$ behave in the same manner as block $\rho_{core}$, except that $\tilde v$ fixes all but two of the bits of $v_1$ rather than $v_5$. If $i \neq 1$, then, for the most part, the argument remains the same. We need only consider what happens if the position, $\ell$, is in one of the eight sub-blocks. As mentioned before, half of the bits of $v'$ are not modified by the sub-block, while the other half are used as “scratch”. Again, without loss of generality, we assume that the sub-block does not modify the first half of $v'$. As before, $\tilde v'$ fixes the first half of $v'_4$. We enumerate on all choices for the first half of $v'_4$. This enables us to reverse the operations of the sub-block on the “scratch”, fixing the second half of $v'_4$—as in the third case. This implies that $|\Omega_{\tilde v, \ell}| = O(2^{4n})$, and completes the proof.

\[\square\]

6 Odds and Ends

Proof. (of Lemma 13)

We have to prove that for all $w \geq 1$ the mixing time of $G_{2,n}^{(w)} = sc(\Sigma_w, X(2))$ is $O(n \log n)$.

Given a $2$ by $n$ matrix with rows $s, t$, we change basis to $s, u$ with $u = s \oplus t$. Let $i \in [n]$ be a random coordinate, and consider the action of a width $w$ permutations XORing the $i$-th bit with a random function $h$ on $w$ distinct coordinates from $[n] \setminus \{i\}$. We claim that its action on $s, u$ is the same as XORing the $i$-th bit of $s$ and $u$ with two independent random bits $\alpha_s$ and $\alpha_u$ respectively. The bits $\alpha_s, \alpha_u$ are one with probability $1/2$ and $p_\ell = 1 - \prod_{j=1}^{w} (1 - \frac{\ell}{n-1})$ respectively, where $\ell$ is the number of ones in $u$ not counting the $i$-th bit. To see that this is indeed the resulting walk we observe the fact that if $s$ and $t$ differ on one of the input bits of the random function $h$, then the
value of the \(i\)-th coordinate of \(s\) and of \(t\) change independently with probability half. Otherwise they change simultaneously with probability \(1/2\).

The \(u\)-component of this walk is a variant of the Aldous cube, and by the comment at the end of [5] it follows that this walk mixes in \(O(n \log n)\) time. We are left to show that in this time the walk on both components mixes. The way to see it is to notice that in \(O(n \log n)\) time the event \(A\) where the indices \(i\) assume all possible values in \(1, 2, \ldots, n\) (coupon collector) happens with high probability. Now since the bits \(\alpha_s\) are independent of \(\alpha_u\), we get that even when we condition over the walk on the \(u\) component, the \(s\) component achieves uniform distribution conditioned on \(A\), which ends the proof.

**Lemma 18.** Let \(A\) be an event such that \(\Pr[A] \geq 1 - \epsilon\), and let \(Z\) be a random variable over a domain \(\Omega\) such that \(d(Z|A, \text{uniform}) \leq \epsilon\). Then \(d(Z, \text{uniform}) \leq 2\epsilon\).

**Proof.**

\[
d(Z, \text{uniform}) = \max_{S \subseteq \Omega} \Pr[Z \in S] - \frac{|S|}{|\Omega|} \leq \max_{S \subseteq \Omega} \Pr[Z \in S|A] + \Pr[A] - \frac{|S|}{|\Omega|} \leq \epsilon + d(Z|A, \text{uniform}) \leq 2\epsilon.
\]

**Lemma 19.** Let \(X\) be a random variable and \(A\) an event. Then \(\Pr[X|A] \leq \Pr[X]/\Pr[A]\). (Follows from the definition of conditional probability.)

### 7 Some concluding remarks

Let us review what we currently know about the spectral gap of the Markov chain \(P = P_{k,n}^\Sigma\). By Theorem 2, \(\text{gap}(P) \leq \Omega(1/n^2k)\). On the other hand, \(\text{gap}(P)\) is nonincreasing in \(k\) by the lifting argument from Section 3. Since for \(k = 1\), \(P\) is the standard random walk on the cube, we have that \(\text{gap}(P) \geq 1/n\).

In general, a generating set \(S\) for which the spectral gap is large becomes more difficult as \(k\) increases, until the largest conceivable \(k\), which is \(2^n - 2\). In this case, this is the random walk on the Cayley graph of the alternating group \(A_N\) for \(N = 2^n\) with the generating set \(S\). It is open whether one can find a constant size set for which \(A_N\) is an expander. [16] Problem 10.3.4. On the other hand, by Alon and Roichman [2], a random set of permutations of size \(O(N \cdot \log N)\) will almost surely have a constant spectral gap. Although smaller expanding sets for \(A_N\) are not known to exist, the general belief is that such sets exist; Rozenman, Shalev, and Wigderson assume the existence of an \(N^{1/30}\) expanding set for \(A_N\), [18] section 1.4.

Our results suggest that width 2 permutations may be used to construct an \(O(\log^3 N)\) expanding set for \(A_N\). However, several obstacles stand in the way of achieving this goal. The first one is to prove that for width 2 permutations the spectral gap does not deteriorate with \(k\), as we believe, and is \(\Omega(1/n)\) for all \(k\). The second problem is to achieve a constant gap. To this end, one has to overcome the inherent and obvious weakness of the width 2 simple permutations. Namely, that their action depends only on two coordinates and changes only one. This leads to poor expansion.

---

6The problem of finding a constant size expanding set for \(A_N\) or \(S_N\) is equivalent.
because there is only a small chance that the action will flip a specific bit or increase the distance between two similar vectors. One approach to avoiding this problem is to replace the standard set of generators of the cube $e_1, \ldots, e_n$ with some expanding set of size $O(n)$. Such an expanding set for the cube can readily be constructed from the generating matrix of a good code \cite{7}, and could then be used to define an $O(n^2)$ expanding set of permutations.
