Abstract

We study quasi-ballistic heat transfer through air between a hot nanometre-scale tip and a sample. The hot tip/surface configuration is widely used to perform non-intrusive confined heating. Using a Monte Carlo simulation, we find that the thermal conductance reaches 0.8 MW m⁻² K⁻¹ on the surface under the tip and show the shape of the heat flux density distribution (nanometre-scale thermal spot). These results show that a surface can be efficiently heated locally without contact. The temporal resolution of the heat transfer is a few tens of picoseconds.

Understanding the heat transfer between a hot tip and a substrate is a key issue in nanometre-scale devices operating at high temperatures such as scanning thermal microscopy (SThM) [1, 2] and also thermally assisted data storage [3]. Indeed, several of the future methods for writing or reading information are based on the use of heat transfer between an atomic force microscope (AFM) probe and the disk, because a spatial resolution below 100 nm can be achieved due to the small size of the tip [4]. Contact heating can be used for writing by melting the substrate [3]. But the tip–sample contact is then responsible for tip damage [5]. Moreover, in such devices, heat is dissipated over large distances if the hot part of the tip is micrometric [6]. Non-contact localized heating through air with a moving medium could be a solution. Different methods such as Joule (e.g. [7]) or Peltier heating (e.g. [8]) are possible for heating the extremity of the tip. A quantitative estimation of the heat transfer through air clearly appears as a key step for designing thermally assisted data storage techniques. In this paper we report a calculation of the heat transfer between the apex of a tip and a surface. We discuss the leading mechanism, and the spatial and temporal resolution.

When a hot tip and a cold sample are not in contact, heat can be exchanged through conduction [8] or radiation [9]. The radiation contribution can be evaluated using the model described in [9]. The heat conduction cannot be modelled by classical Fourier diffusion because the air mean free path (MFP) is on the order of the average distance between the tip and the sample. Neither is pure ballistic transfer valid: this problem has to be solved in the intermediate regime. Three-dimensional (3D) effects also have to be included to observe the impact of the tip geometry. We therefore use a Monte Carlo approach associated with the linear response theory in order to solve space-and time-dependent problems directly. This model also allows us to study the time dynamics of heat conduction through the air gap.

We now describe how the radiation is evaluated. The radiation between a sphere with the same volume as the heated zone of the tip and a surface may be calculated for different materials. For a distance of 20 nm between the centre of the sphere at 800 K and the surface of the same material at 300 K, we found a flux of $5 \times 10^{-17}$ W for silicon and $1 \times 10^{-14}$ W for silver. As discussed in [9], this flux can be increased if both the tip and the surface have an infrared active optical phonon resonance. For glass, we found $9 \times 10^{-9}$ W.

We now turn to the description of the conduction model. Its basis consists of calculating the time evolution of the local heat flux on the sample \( q_{\text{th}}^\text{tip}(r, t, T_{\text{tip}}) \) due to the impulse of molecular flux leaving the tip. The heat flux response \( q_{\text{th}}(r, t) \) to a given molecular flux excitation \( q_{\text{th}}^\text{tip}(\tau) \) is then given by

\[
q_{\text{th}}(r, t) = \int_0^\tau \left( q_{\text{th}}^\text{tip}(r, t - \tau, T_{\text{tip}}(\tau)) \right) d\tau
\]

where \( q_{\text{th}}^\text{tip}(r, t, T_{\text{tip}}) \) plays the role of a susceptibility. \( S_{\text{tip}} \) is the area of the heated part of the tip.

Let us now discuss how the susceptibility is computed using a Monte Carlo approach. The heat transfer is due to air molecules, which are, to a first approximation, nitrogen molecules. A molecule is considered to carry its heat to the tip by transferring its molecular flux to the tip surface. The sample and gas are at the ambient temperature \( T \), where \( m \) is Boltzmann’s constant [11]. A cold molecule is heated when it is deflected by the action of the tip and then it flies with a velocity chosen according to the very isotropic distribution of velocity of the beam of the tip. The emission laws for velocity \( v \) and direction described by the cylindrical angles \( \theta \) and \( \varphi \) are derived from the equilibrium molecular flux leaving the tip at normal incidence:

\[
q_{\text{th}}^\text{tip}(r, t, T_{\text{tip}}) = \frac{n_{\text{tip}}}{2\pi m k_B T_{\text{tip}}} \int_{0}^{\infty} v^3 \exp \left( \frac{-m v^2}{2 k_B T_{\text{tip}}} \right) dv
\]

where \( m \) is the diatomic mass, \( n_{\text{tip}} \) is the number of molecules per unit volume derived from the condition of null molecular flux at the tip surface. The sample and gas are at the ambient temperature \( T_s \). The incident molecular flux is given by equation (2), where \( n_{\text{tip}} \) is replaced by the number of molecules per unit volume in the gas, denoted \( n_g \), and \( T_{\text{tip}} \) is replaced by \( T_s \). A molecule leaving the tip is replaced by a total number of molecules \( n_{\text{tip}} \) by the Monte Carlo simulation and leaves the area with the mean energy \( E \). We therefore assume that the kinetic energy is fully absorbed. Those molecules are considered to leave the tip at the same initial time, and the arrival time \( t \) is given by their flight time. The calculated susceptibility is a statistical average over \( N \sim 4 \times 10^8 \) molecules. At \( T_{\text{tip}} = 800 \, \text{K} \), the mean power given by the tip to air molecules is about 90 nW.

Figures 2(a) and (b) represent the heat flux density deposited on the sample surface when the tip is in contact (top) and when \( d = 10 \, \text{nm} \) (bottom) in a steady-state analysis. This is obtained by temporal integration of the susceptibility. The characteristic size (full width half maximum, FWHM) of the heated zone in contact is a square of edge 35 nm. This corresponds to the best spatial resolutions for SThM and also to disk densities of up to Tb/in². The geometry of the heat flux density reproduces the square shape of the tip projection in the case of contact. For heights larger than \( d = 10 \, \text{nm} \), the imprint of the tip is lost and the deposited energy becomes axisymmetric. This shows that the shape of the tip no longer influences the heat transfer. This behaviour is still observed if we do not include collisions in the model. It follows that it is due to the isotropy of the velocity distribution of emitted molecules. Previous models based on vertical projection might not reproduce this phenomenon correctly under \( d = 10 \, \text{nm} \) [8]. Levels of heat flux densities obtained for a tip temperature of 800 K are higher than 45 MW/m² in contact. The values that we found correspond to a total power on the order of 10 nW, much larger than the radiation contribution when using silicon. The temperature of a 10 nm thick film of insulator material (thermal conductivity \( k = 1 \, \text{W m}^{-1} \text{K}^{-1} \)) would be increased by about 80 K in 1 μs in contact and by 25 K when \( d = 10 \, \text{nm} \). This indicates that heating through air with a moving medium is feasible. In figure 2(c), we report the radial distribution of the heat flux density. In contact, a linear decrease is found until 35 nm. As seen in the inset, the FWHM of the thermal spot increases by more than 10 nm when \( d \) increases from \( d = 0 \) to 20 nm. The comparison of dashed lines and plain lines shows that the effect of the collisions is to reduce the heat flux further.

Figure 3 represents the evolution of the susceptibility [12] \( q_{\text{th}}^\text{tip}(r, t, T) \) integrated over a square surface of side \( s = 15 \, \text{nm} \) under the tip with \( l = 40 \, \text{nm} \) and \( h = 20 \, \text{nm} \) at various heights \( d \). The minimum heating time is equal to the time width of the flux response. This is on the order of 10 ps. This is not a limiting factor for writing applications, since this time is much longer than the time needed for writing applications. This would allow the use of the heating process to obtain harder sphere media [10]. A molecule may undergo several collisions before it reaches the sample surface. Hot molecules that remain in the gas are discarded and the contribution of collision partners to the tip–sample heat flux is neglected. Finally, the thermal flux received by an element \( dx \times dy \) of the surface is

\[
\langle q_{\text{th}}^\text{tip}(r, t, T) \rangle = \frac{E(r, t)}{\delta x \delta y} N
\]

where \( N \) is the number of emitted molecules and \( E(r, t) \) is the net energy transferred by the molecules emitted by the tip and falling in the area \( \delta x \delta y \) during the time interval \( \delta t \).

Each molecule arrives with an energy determined by the Monte Carlo simulation and leaves the area with the mean energy \( T_s \). The accommodation factor is bigger than \( \alpha = 0.87 \) (see reference [11]).
smaller than the conduction timescale in the tip. As shown in the inset, the power given to the sample surface at $d = 30$ nm is half of what is found in a pure ballistic calculation and 65% for a square of edge 25 nm. Although the susceptibilities are not qualitatively different, it is necessary to take into account effects of collisions. Note that the collisions are responsible for the loss of 70% of the power in comparison to the ballistic case, when the height $d$ is equal to the mean free path.

In summary, we have studied the heat transfer through air between the hot extremity of a tip and a surface. The hot tip/surface configuration is widely used to heat a surface locally. We find that, for silicon, air conduction dominates the heat transfer. The values of the heat flux density reach 0.5 MW m$^{-2}$ K$^{-1}$ at a distance of 35 nm from the axis of the tip. The timescale of the conduction heat transfer is on the order of tens of picoseconds. These figures show that heat transfer through air at distances on the order of 10 nm is sufficient to allow non-contact scanning thermal microscopy or thermally assisted data storage.
