Abstract

Fruit set of plants largely depends on the biosynthesis and crosstalk of phytohormones. To date the role of cytokinins (CKs) in the fruit development is less understood. Here, we showed that parthenocarpic fruit could be induced by 1-(2-chloro-4-pyridyl)-3-phenylurea (CPPU, an active CK) in tomato (Solanum lycopersicum cv. Micro-Tom). The fresh weight of CPPU-induced parthenocarpic fruits was comparable with that induced by GA1. Importantly, CPPU-induced parthenocarpic was found to be compromised by simultaneous application of paclobutrazol (a GA biosynthesis inhibitor), and this effect could be restored by exogenous GA1. Like pollination, CPPU-induced fruit showed enhanced accumulation of GA1,3 and indole-3-acetic acid (IAA), which were accompanied by elevated expression of GA biosynthesis genes like SlGPS, SlGA20ox1, SlGA20ox2 and SlGA3ox1, and IAA biosynthesis gene ToFZY. Elevated GAs level in CPPU-induced fruits was also associated with down-regulation of GA inactivation genes, namely SlGAIp, SlGA2ox1,2,3,4,5 in comparison with untreated control. These results suggested that CKs may induce parthenocarpy in tomato partially through modulation of GA and IAA metabolisms.

Figure 3. Changes in the concentration of active GA (GA1,3) (ng g−1 FW) in the CPPU-induced and pollinated fruits. All the ovaries and fruits were collected at 5, 10, 20 DAA, and applied with CPPU (10 µl/ovary, concentration of CPPU 100 mg L−1). UP, unpollinated; P, pollinated. All experiments were performed with three biological replicates and two technical replicates. Significant differences (P<0.05) between treatments are indicated by different letters according to Tukey’s test.

Introduction

Fruit set is a vital phase of plant development encompassing transition of quiescent ovaries to fertilized and fully grown fruits [1–3]. It is usually achieved through successful pollination and fertilization or via parthenocarpy [1]. Parthenocarpy is an important physiological event and largely depends on the coordinated action of inherent hormones produced in the unpollinated ovaries [4,5]. Enhanced biosynthesis of auxins (Aux), gibberellins (GAs) and cytokinins (CKs) has been observed in pollinated ovaries and in the ovaries of the parthenocarpic mutants such as pat, pat2 and pat3/pat4, in tomato [3,6–9]. Transcripts of the Aux and GAs responsive genes were up-regulated within 48 h after pollination in tomato ovaries, thereby suggesting the induction of Aux and GA signaling pathways by pollination [6]. Several lines of evidences showed that Aux and GAs are critically involved in fruit set and fruit development in tomato plants [7,10–12]. In practice, Aux and GAs are widely used to improve the fruit set.
under suboptimal growth conditions, which limits pollination and/or fertilization in commercial production of horticultural crops [1,8,13].

Pollination is usually associated with an increased level of GAs, which is accompanied by an induction of GA biosynthesis genes CPS (copalyldiphosphate synthase) and GA20-oxidase genes in tomato ovaries [9,14]. Fruit set in both pollinated wild-type and unpollinated parthenocarpic mutant tomato ovaries was reduced by the application of GA biosynthesis inhibitors, and this effect was found to be reversed by the exogenous application of GA$_3$ [7,14]. On the other hand, overexpression of Aux biosynthesis genes or loss of function of components in the Aux signaling cascade showed altered parthenocarpic capacity [15,16]. A recent study elucidated that Aux could induce fruit set and growth in tomato, at least in part through enhancing GA biosynthesis, probably by decreasing GA inactivation activity [17]. It appears that the crosstalk between Aux and GAs plays a critical role in the fruit development.

Besides GAs and Aux, other phytohormones such as CKs, abscisic acid (ABA) and brassinosteroids (BRs) have also been shown to play roles in fruit set and subsequent fruit growth [18–20]. For instance, CKs play a critical role in the stimulation
Figure 2. Response of unpollinated tomato ovaries to CPPU and GA₃ treatment (10 µl/ovary; Concentration of CPPU 100 mg L⁻¹ and GA₃ 200 mg L⁻¹). (A) Response of fruit FW to GA₃, CPPU or GA₃ plus CPPU. (B) Response of fruit pericarp thickness to GA₃, CPPU or GA₃ plus CPPU. (C) Transverse sections of fruit treated with GA₃, CPPU or GA₃ plus CPPU. CPPU and ZT were applied at anthesis. (D) Microscopic analysis of the pericarp in 20 DAA fruits. UP, unpollinated; P, pollinated. Fruits were collected 20 days after CPPU and/or GA₃ application. Values are means of three replicates with 10 ovaries as a replicate (±SD). Significant differences (P<0.05) between treatments are indicated by different letters according to Tukey’s test.

of cell division throughout the plant life cycle. In agreement with the concomitant increase in CKs level, transcripts of the CK biosynthesis genes was induced by pollination in tomato ovaries [3,6,21–23]. Interestingly, the effects of different hormones on the induction of fruit set vary with plant species. For example, Aux and GAs had less potential to induce parthenocarpic fruit growth than CKs in crops such as cucumber, kiwi fruit, melon and pear [24–29]. Work in our laboratory revealed that parthenocarpy induced by CKs and BRs was associated with increased transcripts of CyCD3, a gene involved in the cell cycle in plants [18,30]. However, lack of genomic information and mutant resource largely hinders the elucidation of the mechanism of parthenocarpy in these plant species. Additionally, the molecular mechanism by which CKs crossstalk with other hormones in the early phase of fruit development also remains elusive.

Although increased CKs accumulation was observed at the early stage of fruit development in tomato [3], the potential role of CKs in fruit set has not been clarified. Keeping this in mind, the present study hypothesizes that CKs may induce parthenocarpic growth via altering the endogenous metabolic profiles of GAs and Aux in tomato ovaries. To validate the above hypothesis, dynamics of endogenous GAs and indole-3-acetic acid (IAA) and the expression patterns of key genes of GAs and IAA metabolism in tomato ovaries after pollination or CKs treatment were examined. Our results showed that CKs-induced parthenocarpic fruit growth could be partly attributed to the altered metabolism of GA and IAA.

Materials and Methods

Plant material and growth conditions

Solanum lycopersicum cv. Micro-Tom plants were used in the present study. Seeds were obtained from the Tomato Genetics Resource Center at University of California (Davis). The seeds were germinated in trays filled with peat and vermiculite (1:1, v/v). On the appearance of the first two truly expanded leaves, seedlings were transplanted into plastic pots (one seedling/pot, 15 cm diameter and 15 cm deep) containing the same medium. Seedlings were kept in growth chambers and watered with half-strength Hoagland's solution. The growth conditions were as follows: temperature 25/17°C (day/night), a 12-h photoperiod, and light intensity of 200 µmol m⁻² s⁻¹. Only one flower per truss and the first two were left per plant for the experiment, as previously described [17]. All the unselected flowers were removed 2 days before anthesis.

Hormone treatments and sampling

Flowers were emasculated 2 days before anthesis to prevent self-pollination except those used for the pollination treatment. t-Zeatin (ZT, Sigma-Aldrich, USA), 1-(2-chloro-4-pyridyl)-3-phenylurea (CPPU, Sigma-Aldrich, USA) and GA₃ (Sigma-Aldrich, USA) dissolved in a solution containing 5% ethanol and 0.1% Tween 80 were applied to unpollinated (UP) ovaries at the defined concentrations, 10 µl per ovary on the day equivalent to anthesis. Paclobutrazol (PAC, Sigma-Aldrich, USA) was applied to the roots in the nutrient solution at 10⁻⁵ M at the rate of 200 ml per plant every 2 days, as previously described [12,17]. Ovaries treated with the solvent alone were set as unpollinated control. At 1, 3, 5, 10 and 20 days after anthesis (DAA), ovaries were collected, frozen in liquid nitrogen, and stored at -80°C respectively, until further analysis.

Light microscopy and morphometric analyses

Fruits were sampled at 20 DAA. The pericarp was fixed in a mixture of 70% ethanol, formaldehyde, and acetic acid (90:5:5 by volume). A 5-mm-thick slice was cut out from the pericarp and embedded in paraffin. The transverse sections of 9-µm-thick were prepared from slices using microtome. The sections were mounted, stained with toluidine blue, and photographed under an Olympus motorized system microscopes (BX61, Olympus Co., Tokyo, Japan).

Analysis of gibberellin (GA₁₃) and IAA contents by ELISA

The extraction, purification and immunoassay of GA₁₃ and IAA were performed using GA₁₃ and IAA ELISA kit (China Agricultural University, Beijing, China) as described previously [29,31,32]. In brief, approximately 0.2 g fresh weight (FW) of ovaries or 2 g of fruits at different developmental stages was used for GAs and IAA extraction.
Figure 5. Transcript level of genes encoding enzymes of GA biosynthesis pathway as influenced by pollination and CPPU treatment. (A) SlGPS, SlCPS, SlGA3ox1 and SlGA3ox2 genes. (B) SlGA20ox1, SlGA20ox2, SlGA20ox3 and SlGA20ox4 genes. UP, unpollinated; P, pollinated. CPPU (10 µl/ovary, concentration of CPPU 100 mg L\(^{-1}\)) was applied at the anthesis. Equivalent to anthesis was set as 0 d. All experiments were performed with three biological replicates and two technical replicates. Gene expression analysis

Transcript levels of genes involved in GA biosynthesis (SlCPS, SlGPS, SlGA20ox1, SlGA20ox2, SlGA20ox3, SlGA20ox4, SlGA3ox1 and SlGA3ox2), GA catabolism (SlGA2ox1, SlGA2ox2, SlGA2ox3, SlGA2ox4 and SlGA2ox5) and signaling (SlGA INSENSITIVE DWARF1 (SlGID1)), and GA-inducible genes such as SlGibberellin-stimulated transcripts1 (SIGAST1) and SlDELLA were analyzed with quantitative Real Time-Polymerase Chain Reaction (qRT-PCR). The primers used for corresponding genes were designed as described by Serrani et al [17]. The primer of IAA biosynthesis gene ToFZY (a tomato gene encoding a flavin monoxygenase involved in tryptophan-dependent Aux biosynthesis pathway) was designed according to Mariotti et al [3]. All these primers used were listed in Table S1. The expression of all the genes was analyzed by qRT-PCR analysis.

Total RNA was extracted from the ovaries/fruit using the Trizol reagent according to the supplier’s instructions. Total

Figure 6. Transcript levels of genes encoding enzymes of GAs catabolism in unpollinated, pollinated and CPPU-induced parthenocarpic fruits. CPPU (10 µl/ovary, concentration of CPPU 100 mg L⁻¹) was applied at the anthesis. UP, unpollinated; P, pollinated. Equivalent to anthesis was set as 0 d. All experiments were performed with three biological replicates and two technical replicates. Significant differences (P<0.05) between treatments are indicated by different letters according to Tukey’s test.

Figure 7. Transcript levels of genes encoding GA receptor and responsive genes in unpollinated, pollinated and CPPU-induced parthenocarpic fruits. CPPU (10 µl/ovary, concentration of CPPU 100 mg L⁻¹) was applied at the anthesis. UP, unpollinated; P, pollinated. Equivalent to anthesis was set as 0 d. All experiments were performed with three biological replicates and two technical replicates. Significant differences (P<0.05) between treatments are indicated by different letters according to Tukey’s test.

doi: 10.1371/journal.pone.0070080.g007
RNA was reverse-transcribed using ReverTra Ace qPCR RT Kit (Toyobo, Japan) following the supplier's recommendation. qRT-PCR was performed using the iCycler iQ™ Real-time PCR Detection System (Bio-Rad, Hercules, USA) using iQ SYBR Green SuperMix (Takara, Japan). To minimize sample variation, the mRNA expression of the target gene was normalized relative to the expression of the housekeeping gene actin. The quantification of mRNA levels was based on the method of Livak and Schmittgen [33].

Statistical methods

Each treatment had at least 30 flowers with 10 flowers as a replicate. Measurements for the GA1+3 and IAA contents, and qRT-PCR were performed using at least three biological replicates with two technical replicates. Data were statistically analyzed using analysis of variance (ANOVA), and tested for significant (P<0.05) treatment differences by Tukey’s test.

Results

CKs induce parthenocarpic fruit set and development

To investigate whether CKs can induce parthenocarpic fruit growth in tomato, we applied t-zeatin (ZT) and 1-(2-chloro-4-pyridyl)-3-phenylurea (CPPU) each at 1, 5, 10, 50 and 100 mg L⁻¹, which is equal to a dose of 10, 50, 100, 500 and 1000 ng per ovary, respectively, to unpollinated ovaries of tomato plants at anthesis. The unpollinated ovaries treated with water alone (served as a control) were unable to grow (Figure 1A, B), whereas fruit set percent of pollinated ovaries was near 100%. In sharp contrast with the control, both ZT and CPPU were able to induce parthenocarpic growth at all the concentrations tested, percentage of fruit set and fruit fresh weight (FW) was, however, found to be increased with a dose-dependent manner. Moreover, applications of ZT and CPPU at 100 mg L⁻¹ were found to be most effective for fruit set, with a percentage of fruit set of 80% and 100%, respectively (Figure 1A). The higher efficacy of CPPU over ZT led us to choose this cytokinin for our further research.

In the following study, we compared the efficacy of CPPU (100 mg L⁻¹) and GA3 (200 mg L⁻¹) on the induction of parthenocarpic fruit. Both CPPU and GA3 treatments induced seedless fruits (Figure S1). The weights of both GA3- and CPPU-induced parthenocarpic fruits were less than that of pollination-induced fruits, whilst the pericarp thickness of CPPU-induced fruit was comparable to those of GA3-induced fruits (Figure 2A). Co-application of CPPU and GA3 showed additive effects on the fruit weight, with fruit weight increased by ca. 35% as compared with CPPU or GA3 alone. In addition, the pericarp was thicker than those recorded for application of CPPU and GA3 alone or pollination treatment due to the larger cells in the pericarp (Figure 2B, C, D).

Parthenocarpic fruit set induced by CK contains high levels of GA1+3

To determine whether CPPU-induced fruit set in tomato was dependent on GAs, we analyzed the dynamics of endogenous GA1+3 in unpollinated ovaries, pollinated ovaries and unpollinated ovaries with the application of CPPU at 100 mg L⁻¹. There was no significant change in GA1+3 content after anthesis in the unpollinated ovaries. In contrast, GA1+3 contents increased sharply at 5, 10 and 20 days after anthesis (DAA) in pollinated ovaries. A significant increase in GA1+3 content was also recorded for CPPU-treated ovaries at 5, 10 and 20 DAA, although the increase in GA1+3 content in CPPU-treated ovaries was less remarkable when compared with pollinated ovaries (Figure 3). These results suggest that the increase in GAs content in CPPU treated ovaries was involved in parthenocarpic fruit set.
GA biosynthesis inhibitor reduces CK-induced parthenocarpic fruit growth

To determine the role of GAs in CPPU-induced fruit set and fruit development, we applied paclobutrazol (PAC), a GA biosynthesis inhibitor to pollinated and unpollinated ovaries with or without GA \(_3\) and CPPU through soil drench. The PAC application alone completely inhibited growth of pollinated ovaries (Figure 4). The PAC-induced abortion in pollinated ovaries was, however, restored by the co-application of GA \(_3\). In contrast, CPPU was found to be much less effective in inducing parthenocarpic fruit growth than GA \(_3\) when the plants were co-applied with PAC. Furthermore, the co-application of PAC, GA \(_3\) and CPPU induced parthenocarpic fruit with the fresh weight comparable to that induced by CPPU. These results showed that GA biosynthesis plays an important role in CPPU-induced parthenocarpic fruit set and growth in tomato.

CK increases the endogenous level of GA with up-regulation of GA biosynthesis genes

To examine whether CPPU-induced increase in GA pools of unpollinated fruit was related to alteration of expression of genes involved in GA metabolism, qRT-PCR analyses were performed at 1, 3, 5, 10, 20 DAA. We first investigated the transcripts of genes involved in GA biosynthesis. Pollination and CPPU treatments differentially influenced the transcripts of these genes. Generally, pollination and CPPU treatments up-regulated the transcripts of \(\text{SIGPS} (\text{geranyl pyrophosphate synthase})\), \(\text{SIGA3ox1} \text{[3b-hydroxylase (3OH-1)]}\), \(\text{SIGA20ox1} \text{(gibberellin \text{20-oxidase-1})}\), \(\text{SIGA20ox2} \text{(gibberellin \text{20-oxidase-2})}\), \(\text{SIGA20ox3} \text{(gibberellin \text{20-oxidase-3})}\), and \(\text{SIGA20ox4} \text{(gibberellin \text{20-oxidase-4})}\) but affected the transcript of \(\text{SIGPS} (\text{copalyl diphosphate synthase})\) to a lesser degree. Interestingly, such changes in transcripts were dynamic and pollination induced the transcripts of the many genes such as \(\text{SIGPS, SIGA3ox1}\) and \(\text{SIGA20ox}\) earlier than CPPU. In contrast, down-regulation of \(\text{SIGA3ox2} \text{[3b-hydroxylase (3OH-2)]}\) was observed for all time points analyzed with the exception of CPPU-treated ovaries at 10 DAA (Figure 5A).

We then analyzed the transcripts of \(\text{SIGA2ox1}, \text{SIGA2ox2}, \text{SIGA2ox3}, \text{SIGA2ox4}\) and \(\text{SIGA2ox5}\) genes (gibberellin \text{2-oxidase 1-5}) which encode GAs inactivating GA2-oxidases, in unpollinated, pollinated and CPPU-treated unpollinated ovaries. Increased transcripts of these genes were observed in pollinated or CPPU-treated ovaries at 1 DAA, except for \(\text{SIGA2ox2}\). However, GA inactivation genes showed down-regulation in pollinated and CPPU treated ovaries at 3, 5, 10 and 20 DAA with the exception of \(\text{SIGA2ox2}\) and \(\text{SIGA2ox5}\) at 3 DAA. The transcripts of \(\text{SIGA2ox2}\) showed decreases of 89% and 94% in pollinated and CPPU-treated ovaries at 5 DAA, respectively (Figure 6). These results suggest that, like pollination, CPPU could increase GAs content in the fruits at least in part through the induction of GA biosynthesis genes and suppression of GA inactivation genes.

CK alters expression of GA-responsive and signal transduction genes

To examine the crosstalk between CKs and GAs during fruit set and subsequent fruit development in tomato, we analyzed the effects of pollination and CPPU treatments on the expression of several putative GAs response and signal transduction genes in tomato. The transcript of \text{Gibberellin-stimulated transcripts1 (SIGAST1)} was induced in pollinated fruits and CPPU-induced fruits. About 2-fold and 6-fold increase in \(\text{SIGAST1}\) transcript at 5 and 10 DAA in CPPU-induced fruits over untreated control were recorded. However, the expression of \(\text{SIGID1}\) (a homologue of GA receptor \text{GA-INSENSITIVE DWARF1}) was found to be inhibited at all stages of pollinated fruits and CPPU-induced parthenocarpic fruits (Figure 7). The expression level of \text{SIDEALLA}, a negative regulator of GA signaling, was increased by CPPU applications at 1 and 3 DAA over the untreated control. However, \text{SIDEALLA} transcript after 3 DAA was much lower than the untreated control. In contrast, no significant change in the \text{SIDEALLA} transcript was observed in the pollinated ovaries (Figure 7) with the exception at 2 DAA.

Parthenocarpic fruits induced by CK contain high level of IAA

To determine whether Aux biosynthesis could play a role in the CPPU induction of parthenocarpic fruit, the endogenous IAA concentration was determined. As shown in Figure 8A, the concentration of IAA in the pollinated and CPPU-treated ovaries was 3-fold and 8-fold higher than the untreated control at 5- and 10 DAA, respectively. IAA was undetectable in unpollinated ovaries at 20 DAA. In addition, the concentration of IAA in CPPU-induced fruits was decreased after 10 DAA (Figure 8A).

To examine whether the IAA accumulation in pollinated and CPPU-treated unpollinated ovaries was due to the alteration of IAA biosynthesis, we investigated the expression level of \text{ToFZY}, a gene encoding flavin monooxygenase, which is involved in the tryptophan dependent Aux biosynthesis pathway. The \text{ToFZY} expression in CPPU-induced fruits was induced intensely at 1, 5 and 10 DAA by 2-10 folds in comparison with control during the experiment (Figure 8B). These results suggest that CPPU application to unpollinated ovaries could increase the content of endogenous IAA by enhancing the transcription activity of \text{ToFZY}.

Discussion

The Aux and GAs have been well documented for their capacity in inducing parthenocarpic fruit set in tomato plants [1,7,13]. Our studies showed that CKs may induce parthenocarpic in tomato partially through modulation of GA and IAA metabolisms. This conclusion is based on the following evidences: (1) CPPU, an active CK, could induce fruit set efficiently when applied directly to the unpollinated ovaries; (2) the effect of CPPU on parthenocarpoc was compromised when co-applied GA biosynthesis inhibitor (PAC); (3) CPPU could enhance the biosynthesis of GA and Aux; (4) The
It has been revealed that there was a significant increase in the content of endogenous hormones such as Aux, GAs and CKs in tomato ovaries after pollination [3]. In general, genotypes with parthenocarpic capacities usually own higher Aux or GAs contents in the ovary at anthesis [7,8]. In agreement with these observations, exogenous applications of Aux and GAs have been proved to induce parthenocarpic fruit set and growth in tomato [3]. Although an increase in CKs content occurs earlier than that in GAs in pollinated ovaries [3], it remains unclear that whether CKs could induce parthenocarpy or increase GAs in tomato, a model plant species for fruit development research. The data presented in our study elucidated that parthenocarpic fruit could be induced by both ZT and CPPU with the effect comparable to that of GA\textsubscript{3}, suggesting a role of CK in the fruit development in tomato.

In this study, we found that fruit set and development in tomato were largely dependent on the endogenous accumulation of GAs (Figure 3). There was a significant increase in GAs level in the ovaries after pollination. The application of PAC on pollinated ovaries resulted in poor ovary growth and decreased GAs accumulation, indicating that tomato fruit set and development depend on GAs synthesis after pollination and fertilization [7,12]. There is also evidence that parthenocarpy in tomato induced by Aux application was mediated through GAs [17]. In agreement with this, we found that the development of the pollinated ovary was inhibited by the application of PAC and the effect could be rescued by the co-application of GA\textsubscript{3} (Figure 4). Moreover, CPPU application on unpollinated ovaries showed increased GA\textsubscript{1+3} accumulations (Figure 3). Our studies showed that GA\textsubscript{3} but not CPPU could completely reverse the effects of PAC in pollinated ovaries. Here, it appears that induction of parthenocarpy by CKs in tomato is partly dependent on the accumulation of GAs.

Until now, a subset of GAs has been identified from different plants including tomato fruits. A recent study showed that both GA\textsubscript{1} and GA\textsubscript{3} are two active forms of GAs and play an important role in fruit development in tomato [3]. Here, we showed significantly higher content of GA\textsubscript{1+3} in pollinated and CPPU-treated ovaries over the unpollinated ovaries. These results suggest that CPPU, like Aux, may also participate in regulation of expression of GA metabolism genes and concomitant endogenous GA contents. The gene expression analyses showed that the transcription of genes encoding GPs, GA20ox1, GA20ox2, GA20ox3 and GA3ox1 enzymes of the GA biosynthetic pathway was largely up-regulated by pollination and CPPU treatment over the untreated control (Figure 5). Similar results were also observed in pollinated and Aux-induced fruits [17]. The expression of GA2ox (a multigene family) is associated with the regulation of active GA pool in plants [34] and the expression alterations of GA2ox genes could result in either reduced or enhanced concentration of active GAs in plants [8]. In the present study, we observed down-regulation of GA2ox1, GA2ox2, GA2ox3, GA2ox4 and GA2ox5 in pollinated and CPPU-treated ovaries at 3-, 5-, 10- and 20 DAA, suggesting that the downregulation in the expression of GA inactivation genes might be responsible for the coordinated increase in the concentration of active GA pool in CPPU-induced and pollinated fruits (Figure 6). All these results led us to propose that CKs enhance the GA pool via activation of GA biosynthesis genes and suppression of GA inactivation genes.

GAs and CKs have been shown to exhibit antagonistic effects on numerous developmental processes [35–37], however, the relationships between CKs and GAs in fruit development remain unknown. In this study, we found that transcript of SIGAST1 (Gibberellin-stimulated transcripts1) was induced by pollination and CPPU whilst transcripts of SIGID1, a gene encoding a putative GA receptor [38] were downregulated in pollinated and CPPU-treated ovaries. The CPPU treatment and pollination was found to increase GAs level in the ovaries as observed for AtGID1 in Arabidopsis seedlings [39]. The upregulation of GAST1 was in agreement with those observed in GA\textsubscript{3} and 2,4-D-treated ovaries [17]. In contrast, up-regulation of SIDELLA was observed in our study and this was especially apparent at the first days after the CPPU treatment due to the antagonistic effect of CK on the GAs signaling (Figure 7 [35–37]).

There are intensive crosstalks between phytohormones in plant growth, development and stress responses. Parthenocarpy in tomato induced by Aux application was mediated through GAs [17]. Following the up-regulation of transcripts of Aux biosynthesis genes (ToFY2), we observed increased IAA level in pollination and CPPU-induced fruits over untreated control (Figure 8). These results are in agreement with those of Ohara et al. [27], who found that CPPU-treated kiwi fruit exhibited increased level of endogenous IAA. The Aux signal transduction depends on the degradation of the transcriptional regulators Aux/IAAs, although the function of most of them is not clear yet. The expression level of Aux/IAA genes (IAA1, IAA2, IAA8, IAA9 and IAA14) was increased in response to the 2,4-dichlorophenoxyacetic acid treatment in tomato ovaries [17]. However, loss of function of SlIAA9 exhibited parthenocarpic capability [40], suggesting that the IAA9 transcript level may not be correlated with the protein level or, alternatively, that Aux mediated parthenocarpic induction is not mediated by IAA9 downregulation [17]. Furthermore, it is unclear whether the expression of GA metabolism genes and associated GAs accumulation are altered by these Aux signaling components, and if so, what is the mechanism. Until now Aux and CKs mutants or chemical inhibitor for their biosynthesis are not available in tomato [17], we failed to elucidate the relation of CKs and Aux with similar methods used to study the relation of the CKs and GAs. The similarity of the transcript profile in CPPU-induced fruit (Figures 5, 6, & 7) and that observed in Aux-induced fruit [17] also suggests that CKs may induce fruit set in a similar way or in an Aux-dependent manner. It is plausible that CKs-induced parthenocarpic growth was attributable to the interaction of CKs, Aux and GAs. CKs could alter their endogenous profiles by modulating expression of the GAs/Aux metabolism genes, and then induce parthenocarpic fruit set in tomato.

It is worth noting that many genes showed different expression timing and pollination could induce the transcripts of many GAs and IAA biosynthesis and catabolic genes earlier.
than CPPU treatment (Figures 5-8). Generally, the locular gel in the ovaries had higher transcripts of GA and IAA biosynthesis and catabolic genes than the pericarp [17]. It is high likely that fertilization, which occurs within the locular gel triggered the transcripts of these genes to a greater degree as compared to CPPU treatment which was applied onto the pericarp. The thicker pericarp in UP + CPPU + GA3 treatment could also be explained by the spatial accumulation of these regulator in the fruits. Foliar application of CPPU and GA3 may accumulate higher in the pericarp, leading to an active cell division and cell enlargement, and finally a higher thickness of the pericarp as compared to the pollinated fruits (Figure 2D).
