ABSTRACT

Iatrogenic non–thrombotic pulmonary embolism is a rare cause of pulmonary embolism. This case demonstrates the unusual imaging findings associated with pulmonary migration of Precipitating Hydrophobic Injectable Liquid, a liquid embolization material most commonly used in interventional neuroradiological procedures. Chest X-ray and CT Pulmonary Angiogram images are shown. The case highlights the importance of a thorough clinical history, including past medical history, when interpreting radiological studies.

Introduction

Non–thrombotic pulmonary embolism (NTPE) can represent a significant diagnostic challenge due to its diverse clinical presentation and varied imaging features [1]. Radiology, in the form of chest X-ray and CT, are the mainstay of accurate and timely identification of this potentially fatal condition [2]. This case reports details an unusual case of iatrogenic NTPE with striking imaging features.

Clinical and radiological observations

A 36-year-old patient presented to the Emergency Department with a 3-day history of shortness of breath on exertion. They reported no chest pain, cough, hemoptysis, or fever. No risk factors for pulmonary embolism were identified. Full blood count, urea and electrolytes, and C-reactive protein were normal. An arterial blood gas demonstrated a mild metabolic acidosis. A chest X-ray was initially considered unremarkable (Fig. 1). Review of the patient’s past medical history and drug history revealed they had commenced acetazolamide 2 weeks previously for intracranial hypertension and their breathlessness was diagnosed as a side effect of this medication [3]. However, given that breathlessness secondary to acetazolamide rarely requires hospital care in younger patients, a CT Pulmonary Angiogram (CTPA) was performed to rule out an alternative cause that was not clearly appreciable on the chest X-ray, such as early COVID-19. This CTPA showed high attenuation material scattered throughout the subsegmental pulmonary arteries of all lung lobes (Fig. 2 and 3). The initial detection of this high attenuation

breathlessness induced iatrogenic ment subsequently was identifi able. phase, material consistent a attenuation highlighted vessels prior to the subsequent CTPA. Two example foci are highlighted by the black arrows.

Fig. 1 – PA chest X-ray taken at time of patient’s presentation. High attenuation foci, most notably within the right lower zone, were assumed to represent end-on vessels prior to the subsequent CTPA. Two example foci are highlighted by the black arrows.

Fig. 2 – Axial (A) and coronal (B) 30 mm maximum intensity projection slices from the patient’s CTPA. The high attenuation embolic material is located in dependent areas. The patient’s embolization had occurred with the patient in a supine position. It is likely the distribution of emboli is consistent with immediate migration of material to these locations while the patient remained supine, analogous to migration of vertebral body cement to anterior portions of the pulmonary vasculature in verteoplasty. The example foci highlighted in Fig. 1 are circled on the coronal (B) image.

material was challenging due to the lack of a non-contrast CT phase, but appropriate windowing made its presence readily identifiable.

On further review of the patient’s past medical history, it was discovered they had undergone embolization of a du- rum arteriovenous fistula with Precipitating Hydrophobic In- jectable Liquid (PHIL) (Micro Vention, CA) 4 months prior to presentation. An additional diagnosis of iatrogenic NTPE was subsequently made and the patient recovered after adjust- ment of their acetazolamide dose. It is believed the patient’s iatrogenic NTPE may have exacerbated their acetazolamide-induced breathlessness. The patient has had no episodes of breathlessness since this presentation.

Fig. 3 – Pulmonary artery reconstruction from the patient’s CTPA showing high attenuation embolic material within dependent regions in all lung lobes.

Discussion

Iatrogenic NTPE encompasses embolization due to a wide spectrum of substances, from well-known biological materials such as amniotic fluid, fat, and septic emboli, to foreign bodies, talc, gas, cement, and glue [4]. PHIL is an established treatment option in interventional neuroradiology for the embolization of cere- bral and spinal arteriovenous malformations and dural fis- tulae. It is also increasingly being used in body intervention [5]. Liquid embolic agents such as PHIL have several advantages over traditional coiling and particulate-based embolization techniques: they solidify when injected into the vasculature, providing a superior mould of their target area’s geometry compared to coiling; the processes of solidification and occlusion are independent of the patient’s physiology, allowing their use in patients with coagulopathies and patients receiving anti-coagulation treatment; and they are considered less likely to fragment and migrate than particulate-based embolic materials. Nevertheless, pulmonary migration remains a recognised but rare complication of embolization with liquid embolic materials [6]. PHIL is comprised of a polymer covalently bonded to an iodine compound (triiodophenol) [7] and so it appears radiopaque on X-ray and CT, presenting a diag- nostic quandary if the patient’s full past medical history is not known.

Conclusion

Iatrogenic NTPE is a rare condition, with chest X-ray and CTPA being crucial in its diagnosis [2]. This case highlights the pos- sibility of NTPE following the use of liquid embolization ma-
Material in distant parts of the body. It also demonstrates the importance of a thorough review of patients’ past medical history when interpreting unusual imaging findings.
