Abstract
Sonolysis and photochemical degradation of different compounds such as chlorinated aliphatic hydrocarbons are among the recent advanced oxidation processes. Perchloroethylene is one of these compounds that has been mainly used as a solvent and degreaser. In this work, elimination of perchloroethylene in aqueous solution by ultrasonic irradiation, and photochemical oxidation by ultra violet ray and hydrogen peroxide were investigated. Three different initial concentrations of perchloroethylene at different pH values, detention periods, and concentrations of hydrogen peroxide were investigated. Head space gas chromatography with FID detector was used for analyses of perchloroethylene. This research was performed in 9 months from April through December 2011.

Results showed that perchloroethylene could be effectively and rapidly degraded by ultrasonic irradiation, photochemical oxidation by ultra violet ray, hydrogen peroxide and a combination of these methods. Kinetics of perchloroethylene was strongly influenced by time, initial concentration and pH value. Degradation of Perchloroethylene increased with decrease in the initial concentration of perchloroethylene from 0.3 to 10 mg/L at all initial pH. The results showed an optimum degradation condition achieved at pH = 5 but did not affect significantly the perchloroethylene destruction in the various pH values. Kinetic modeling applied for the obtained results showed that the degradation of perchloroethylene by ultrasound and photo-oxidation followed first order and second order model. The percentage of removal in the hybrids reactor was higher than each of the reactors alone, the reason being the role of hydroxyl radical induced by ultrasound and photochemical reaction.

Keywords: Perchloroethylene, Ultrasound, Photochemical oxidation, Kinetics models

Introduction
As the number of substances resistant to biodegradation have increased, and the conventional biological methods were unable to complete the treatment of these materials; Therefore, new technologies are required to degrade these resistant molecules to smaller ones. The smaller molecules can be degraded by biological processes [1]. New technologies include advanced oxidation processes such as Fenton, perozone, common use of ozone, UV irradiation, hydrogen peroxide and the use of ultrasonic and photo-catalytic oxidation processes [2]. One category of resistant material to biological degradation is chlorinated hydrocarbons. These materials cause water resources contamination and affect human health. Several studies have been carried out in removing various organic materials from water and aqueous solutions [3-6]. Perchloroethylene (PCE) is a chlorinated hydrocarbon that has been mainly used as a solvent in dry cleaning, degreaser in metal parts manufacturing, and as a precursor in the production of chlorofluorocarbons [7,8]. Perchloroethylene is included in products such as motor vehicle cleaners, stain removers, adhesive and wood cleaners [9,10]. It is a volatile, nonflammable and colorless liquid with a stench that has odor threshold of 1 ppm [9].
The summary of PCE physical properties are shown in Table 1 [11].

Various applications and inappropriate handling and disposal, results in detection of PCE in groundwater, surface water, wastewater, air and food [12-16]. PCE is considered as a probable carcinogenic chemical (Group 2A) to humans [9]. It has also many other adverse health effects [7-12,17], due to which United State Environmental Protection Agency (US.EPA) has set the maximum contaminant level (MCL) and maximum contaminant level goal (MCLG) for PCE as 0.005 mg/L and zero, respectively [18].

Conventional water and wastewater treatment processes have poor efficiency in removal of chlorinated compounds such as PCE [19]. Advanced processes such as membrane process, granular activated carbon and air stripping are effective for removal of chlorinated compounds but they are expensive and transfer the contamination to another phase [20]. A large number of new technologies have been emerged that include sonochemistry, photochemistry, electrochemistry and combined treatment methods such as reductive dehalogenation and biodegradation for the degradation of chlorinated compounds [19]. Advanced oxidation processes (AOPs) are able to degrade chlorinated compounds such as PCE into less harmful compounds by using a combination of ultraviolet radiation, H₂O₂ and ultrasonic waves. Ultrasonic waves are hydroxyl radicals produced during cavitations. Therefore ultrasonic waves are among the advanced oxidation processes [20].

Several studies have been performed on application of photochemical oxidation and sonolysis especially at low concentrations in removal of various pollutants [20-22]; but there are few studies regarding PCE degradation by sonolysis and photochemical oxidation (UVC/ H₂O₂) at micromolar concentration and with a 130 kHz frequency ultrasound. In this work, the degradation rates of PCE at different concentration levels and different pH levels with using an ultrasound bath at 130 kHz frequency and photochemical oxidation with UVC/ H₂O₂ were studied. Continuous models of PCE degradation were also determined.

### Materials and methods

#### Experimental setup

This experimental research was conducted at the Department of Environmental Health Engineering at Tehran University of Medical Sciences between April and December 2011. Ultrasound bath of the solution in a 300 mL glass reactor (Figure 1) was performed with a 130 kHz frequency and acoustic intensity of 2.5 W/cm² (Table 2). The characteristics of UVC reactor (Figure 2) are shown in the Table 3.

Solutions of different concentrations of PCE (0.30, 3 and 10 mg/L) were prepared by dissolving PCE (Merck Co., Germany) in distilled water. The concentrations of H₂O₂ were 10, 50 and 100 mg/L. Temperature was monitored during sonication and maintained constant at 25°C by cooling water. Samples were taken from the ultrasonic and UV reactors at given reaction times (5, 10, 20, 30, 40, 50 and 60 min). The number of samples (regarding pH, time, and concentration as variables) was 63 for each reactor.

| Table 1 PCE properties (EPA, 1994) |

Figure 1 Ultrasonic equipment.
Analytical methods
Analyses were performed by head-space gas chromatography technique. Concentrations of PCE samples were determined through GC-FID analysis (VARIAN CP-3800, Australia). The gas chromatograph was fitted with a CP-Sil 8 CB capillary column (30 m, 0.32 mm ID, 0.25 μm film thickness). The injector temperature was 200°C (held for 1 min) and increased to 100°C at a rate of 16°C/min, held for 5 min. The inlet (200 μL) was operated in 20% split mode. Helium (99.999%) was used as the carrier gas at 1 mL min⁻¹. The lowest detection level (MDL) for PCE analysis by GC with the above mentioned method was 5 μg/L.

Results and discussion
Aqueous solution with initial concentrations of (0.3, 3, and 10 mg/L) for PCE at different pH values were sonicated and photochemically oxidized. The investigation was carried out in six reactors (Table 4). The efficiency at different pH values and kinetic constants in these reactors are illustrated in Tables 5, 6 and 7. The mean removal efficiency in the US/UVC/ H₂O₂ reactor at various concentrations of H₂O₂ is illustrated in Table 8 and Figures 3, 4, 5, respectively.

Regression analysis was used for modeling of perchloroethylene degradation under various reactors. To calculate the effluent concentration and efficiency, the effluent concentration (y), pH (5–9), time (5 to 60 min) and initial concentration (0.3 to 10 mg/L) were considered as independent variables in the model (Table 4) for each reactor.

Parameters that had a significant difference were included in the model (Table 4). These parameters include main variables (pH, primary concentration of PCE and time), interaction and square of main variables. For example, in the US reactor pH, initial concentration (C₀), time, interaction Cin, pH and interaction Cin² time and square Cin and time have a significant difference. These models can be used to calculate the efficiency of those concentrations for which the test was not performed (such as 1 mg/L).

| Reactor          | Concentration (mg/L) | Concentration (mg/L) | Concentration (mg/L) |
|------------------|----------------------|----------------------|----------------------|
|                  | 0.3                  | 0.3                  | 0.3                  |
| US               | 1389                 | 714                  | 595                  |
| UVC              | 153                  | 61                   | 63                   |
| US + UVC         | 420                  | 317                  | 77                   |
| UVC + US + H₂O₂ 10mg/L | 652                  | 451                  | 353                  |
| UVC + US + H₂O₂ 50mg/L | 292                  | 75                   | 30                   |
| UVC + US + H₂O₂ 100mg/L | 25                   | 15                   | 5                    |

Decomposition of PCE in the ultrasonic reactor with 10 mg/L of concentration, UVC, UVC/US and UVC + US + H₂O₂ reactor in all concentrations followed first order kinetics model and in the ultrasonic reactor for 3 and 0.3 mg/L of concentration followed second order kinetics model. Also with increasing the initial concentration of PCE, the apparent first and second order rate constants decreased, indicating non–elementary nature of the photochemical and sonolysis reactions. Most investigators have observed the kinetics of photolysis and sonolysis of pollutants to be first order [23-26].

This dependence of degradation rate constants on initial concentration was similar to other studies [20,23,27]. Degradation rate of PCE at pH = 5 was higher than the other pH levels, but the difference between the other pH values were not significant.

The consumed energy by various reactors for treatment of 1 m³ of contaminated water is illustrated in the Table 9. As shown in Table 9 the energy consumption in the hybrid process (UVC + US + H₂O₂ 100 mg/L) is the lowest, while the Ultrasonic process has a maximum consumed energy.

The hybrid methods showed higher efficiencies compared to the single reactors. The reactors' efficiency from high to low are illustrated below:

\[ UVC + US + H₂O₂\ 10\ mg/L \>
\[ UVC + US + H₂O₂\ 50\ mg/L > UVC + US > \]
\[ UVC + US + H₂O₂\ 10\ mg/L > UVC > US \]

Conclusion

Sonolysis and photochemical degradation of PCE were performed under various experimental conditions such as initial concentration, pH, time of reaction and type of reactor. The reduction of initial concentration of PCE increased the degradation rate of PCE increased and parallel to the increase of initial concentration, the degradation rate constant declined, but the initial pH of the solution did not significantly affect the PCE destruction. It was shown that the application of UVC + US + (H₂O₂ 100 mg/L) could effectively remove PCE in 60 minute. Therefore, the mentioned hybrid process can be considered as process for complete removal of PCE in reasonable detention time. Furthermore, Lower energy consumption of the hybrid process compared to the other methods, make it more feasible to be used in full scale PCE removal practice.

Submit your next manuscript to BioMed Central and take full advantage of:

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution

Submit your manuscript at www.biomedcentral.com/submit
