A PROBABILISTIC REPRESENTATION FOR THE SOLUTIONS TO SOME NON-LINEAR PDES USING PRUNED BRANCHING TREES

D. BLÖMKER, M. ROMITO, AND R. TRIBE

Abstract. The solutions to a large class of semi-linear parabolic PDEs are given in terms of expectations of suitable functionals of a tree of branching particles. A sufficient, and in some cases necessary, condition is given for the integrability of the stochastic representation, using a companion scalar PDE.

In cases where the representation fails to be integrable a sequence of pruned trees is constructed, producing a approximate stochastic representations that in some cases converge, globally in time, to the solution of the original PDE.

1. Introduction

This paper considers stochastic representations for solutions to a large class of semi-linear parabolic PDEs, or systems of PDEs, of the type

$$\partial_t u = Au + \mathcal{F}(u) + f,$$

where $A$ is an operator with a complete set of eigenfunctions, $\mathcal{F}$ is a polynomial nonlinearity in $u$ and its derivatives, and $f$ is a given driving function.

In short, the solution $u$ is expanded into a Fourier series using the eigenfunctions of $A$. This yields (as in spectral Galerkin methods) a system of countably many coupled ODEs for the Fourier coefficients. This ODE system is then solved in a weighted $\ell^\infty$-space, via an expectation over a tree of branching particles. The rules for the branching and dying probabilities arise from the particular PDE being studied. Moreover the PDE determines an evaluation operator $R_t$, acting on the tree $T_k$ of particles rooted at each Fourier mode $k$, so that, under integrability assumptions, the (suitably weighted) $k$’th Fourier mode $\chi_k(t)$ is given by

$$\chi_k(t) = E[R_t(T_k)].$$

This is precisely the method of Le Jan and Sznitman [8] (later extended in Bhattacharya et al. [3], Waymire [17], or Ossiander [13]) where they treated the Navier-Stokes equations in $\mathbb{R}^3$. Earlier papers connecting branching particle systems to PDEs (for instance Skorokhod [15] or Ikeda, Nagasawa, [16]).

Key words and phrases. Branching processes, pruned trees, stochastic representation, PDEs, semi-implicit approximation.
and Watanabe [7], and later McKean [11]) use branching coupled with a diffusion, and the stochastic representation is derived directly without Fourier series, so that the linear operator $A$ is limited to generators of diffusions.

Our first aim is to show that this method applies to a large range of equations. In Section 2 we present three representative examples with quadratic non-linearities. We comment on further generalisations in Section 2.5. Basically any system of parabolic PDEs with polynomial nonlinearities in the derivatives is admissible.

One major drawback of the stochastic representation is that it often fails to exist for large times $t$, although the solution to the PDE may still exist. The problem is that $R_t(T_k)$ may fail to be an integrable random variable for $t \geq t_0$. When deriving a system of ODEs in $\ell^\infty$ space, there is considerable freedom in the choice of weights for the Fourier coefficient under which integrability can be established. See Bhattacharya et al. [3] for an extensive discussion in the case of 3D-Navier Stokes. One way to check integrability is to establish a scalar comparison equation. The finiteness of the comparison equation implies the integrability needed for the stochastic representation to hold. The comparison equation is independent of the weights and represents a worst case scenario with super-linear (explosive) growth. It typically completely ignores most of the structure of the non-linearity in the original PDE.

In Section 3 we establish the stochastic representation under the assumption that it is integrable. In Section 4 we investigate the comparison equation. This typically shows the representation is integrable at small times, or, when there is no linear instability, for all times with small data. For some classes of equations, for example 1d-Burgers equation, we obtain a necessary and sufficient condition for the integrability of the stochastic representation, independent of the choice of weights in Fourier space.

Our second aim is to present an approach to treat cases where integrability fails. The key point is to get rid of the smallness condition on the initial data and the forcing, in order to find a stochastic representation that is global in time. In Bhattacharya et al. [3] the branching trees are pruned after $n$ generations. This gives a stochastic representation of a Picard iteration scheme converging to the original PDE, but, as stated in [3], the existence of the expectation is equivalent to the convergence of the Picard iteration scheme. In another approach, Morandin [12] suggested a clever re-summation of the expectation in order to improve the convergence for large times, but he was only able to rigorously verify the global convergence of his method in a simple example where (1.1) is a one-dimensional ODE. Our approach is to construct sets $\Omega_n$, with $P[\Omega_n] \uparrow 1$ so that

$$\chi_k(t) = \lim_{n \to \infty} E[R_t(T_k) 1_{\Omega_n}].$$

This treats the expectation somewhat as a singular integral, where we have to be careful how to cut out the singularity.
The method we use, explained in Section 5, is to construct a pruned branching tree $T^{(n)}_k$ which will agree with $T_k$ on $\Omega_n$. The expectation for the pruned tree
\[ E[R_t(T^{(n)}_k)] = E[R_t(T_k)1_{\Omega_n}] \]
is well defined and represents the $k$th Fourier mode of the solution to a semi-implicit approximation scheme of the type
\[ \partial_t u^{(n)} = Au^{(n)} + \tilde{F}(u^{(n)}, u^{(n-1)}) + f. \]

We then use PDE techniques to verify that the approximation scheme converges to a solution of the original PDE. Although there are general results for the convergence of such approximations (cf. for example Bjørhus and Stuart [4]) the assumptions are usually quite restrictive. Since stronger arguments are model specific, we present the arguments only in two special cases, namely for a simple quadratic ODE and for Burgers equation. We believe these examples illustrate that the method potentially dramatically extends the range of PDEs for which there is a global stochastic representation. A global result is essential if one wants to study a stochastic representation of the long time behaviour of solutions, for example in terms of stationary solutions or pull-back fixed points. Only in a very simple framework of small initial conditions and uniformly small forcing is it currently possible to derive such results (for the 3D Navier-Stokes equations see Bakhtin [2] and Waymire [17]). The extension of such results to non-trivial cases and the relation with the pruned representation are the subject of work in progress.

2. Abstract setting and examples

We first present an infinite system of ODEs involving a quadratic non-linearity. The system is indexed over $k \in \mathbb{Z}^d$. We then discuss several examples of PDEs on the torus $[0,2\pi)^d$ and recast their Fourier transforms into our abstract ODE setting. We do not present the highest generality possible, but focus instead only an equation with one quadratic nonlinearity, one linear instability and one forcing term. We comment in Subsection 2.5 on a large number of possible extensions, including other domains and boundary conditions, multiple forcing terms and additional nonlinearities, possibly of higher order.

2.1. The general system of ODEs. We consider solutions $\chi(t) : \mathbb{Z}^d \to \mathbb{C}^r$ to the following infinite dimensional system of $\mathbb{C}^r$-valued ODEs
\[ \dot{\chi}_k = \lambda_k \left[ -\chi_k + C_f p_k \chi_k + C_b \sum_{l,m \in \mathbb{Z}^d} q_{k,l,m} B_{k,l,m}(\chi_l, \chi_m) + d_k \chi_k \right]. \]
with $k \in \mathbb{Z}^d$. The constants $\lambda_k > 0$ (which will determine the rate of particle evolution), $p_k, q_{k,l,m}, d_k \in [0,1]$ (which will determine the probabilities of flipping, branching and dying), and $C_f, C_b \geq 0$ (the flipping and branching
constants) are fixed, as are bilinear operators $B_{k,1,m} : C^r \times C^r \to C^r$ satisfying
\[ |B_{k,1,m}(\chi, \chi')| \leq |\chi| |\chi'| \]
for all $\chi, \chi' \in C^r$. The choice of these constants will arise from the Fourier transform of the PDE being studied. We assume throughout that
\[ p_k + q_k + d_k = 1 \quad \text{for all } k \in \mathbb{Z}^d, \]
and
\[ p_k \to 0, \quad q_k \to 0, \quad \text{as } |k| \to \infty \]
where
\[ q_k = \sum_{l,m \in \mathbb{Z}^d} q_{k,l,m}. \]
The data for the equations consists of a time dependent forcing $\gamma = \{\gamma_k(t) : k \in \mathbb{Z}^d, t \geq 0\}$ and an initial condition $\chi(0) = \{\chi_k(0) : k \in \mathbb{Z}^d\}$. We consider the above system in its mild formulation, that is for given data we look for measurable $t \mapsto \chi_k(t) \in C^r$ satisfying, for $k \in \mathbb{Z}^d$,
\[ \chi_k(t) = e^{-\lambda_k t} \chi_k(0) + \int_0^t \lambda_k e^{-\lambda_k (t-s)} \left[ C_f p_k \chi_k(s) + C_b \sum_{l,m \in \mathbb{Z}^d} q_{k,l,m} B_{k,l,m}(\chi_l(s), \chi_m(s)) + d_k \gamma_k(s) \right] ds. \]
Note that we need some regularity of $\chi_k$, in order to make (2.4) well defined.

Remark 2.1. There is considerable flexibility when choosing the constants in the ODE system (2.1). For example, we can adjust the probabilities $p_k, q_{k,1,m},$ and $d_k$ by adjusting the constants $C_b, C_f$ and considering modified forcing data $\gamma$. In particular, in an equation where the probabilities do not add up to 1 in (2.2), it is always possible to adjust $d_k$ and the forcing data so that this constraint holds. Similarly, an equation with $C_f$ and $C_b$ replaced by bounded functions of $k$ can be recast into the form (2.1) by forcing the $k$ dependence into the probabilities $p_k, q_k,$ and $d_k$.

2.2. The d-dimensional Burgers equations. Consider solutions $u(t,x) \in \mathbb{R}^d, \text{ for } t \geq 0 \text{ and } x \in [0, 2\pi)^d$ to the Burgers system
\[ \begin{cases} \partial_t u - \Delta u + (u \cdot \nabla) u = f, \\ u(0) = u^0, \end{cases} \]
with periodic boundary conditions, where $f$ is an external forcing. We restrict ourselves to periodic boundary conditions, as the nonlinearity is easy to compute in the Fourier basis. Nevertheless, other kinds of boundary conditions, for instance like Dirichlet or Neumann, can be treated in a similar fashion (cf. section 2.5).

If we expand the solution
\[ u(t,x) = \sum_{k \in \mathbb{Z}^d} u_k(t) e^{i k \cdot x}, \]
the equation reads in the Fourier coefficients as

\[ \dot{u}_k = -|k|^2 u_k - \sum_{l+m=k} (u_l \cdot m) u_m + f_k, \]

The sum is over all \( l, m \in \mathbb{Z}^d \) satisfying \( l + m = k \). Define a weight function \( w_k = 1 \vee |k|^\alpha \), where \( \alpha > 0 \) will be chosen shortly, and set \( \chi_k = w_k u_k \). Then

\[
\begin{aligned}
\chi_k &= -|k|^2 \chi_k - \sum_{l+m=k} \frac{|m| w_k}{|w_l|} (\chi_l \cdot m) \chi_m + f_k w_k, \\
\chi_k(0) &= u_k(0) w_k.
\end{aligned}
\]

Note that the mode \( \dot{u}_0 \) has no linear dissipation. Below we will add and subtract \( \lambda_0 \dot{u}_0 \) to the equation for \( \chi_0 \), which introduces a linear instability but which allows us to write the equation in our desired abstract form. We note that in dimension \( d = 1 \) this trick is unnecessary: the equations for the zero\(^{th}\) mode decouples, in that it simplifies to \( \dot{u}_0 = f_0 \), and it is then possible to reduce the problem to the case \( f_0 = u_0 = 0 \).

We now show one way to recast (2.6) into the abstract form (2.1). For given \( C_f, C_b, \lambda_0 > 0 \) we define

\[
\begin{aligned}
\dot{\chi}_k &= \begin{cases} 
|k|^2 & k \neq 0, \\
\lambda_0 & k = 0,
\end{cases} \\
\rho_k &= \begin{cases} 
0 & k \neq 0, \\
C_f^{-1} & k = 0,
\end{cases} \\
q_{k,l,m} &= C_b^{-1} \frac{|m| w_k}{|w_l| w_m}, \\
B_{k,l,m}(\chi, \chi') &= -\dot{\chi} (\chi \cdot \frac{m}{|m|}) \chi',
\end{aligned}
\]

whenever \( l + m = k \) (and zero otherwise). Lemma 2.2 below ensures, provided we choose \( \alpha > \max\{d+1, d-1\} \), that \( q_k = \sum_{l,m} q_{k,l,m} < \infty \) and that \( q_k \to 0 \) as \( |k| \to \infty \). Thus by taking \( C_b, C_f \) sufficiently large we have that \( \rho_k + q_k < 1 \) and it remains only to define \( d_k = 1 - \rho_k - q_k \) and \( \gamma_k = (f_k w_k/\lambda_k d_k) \) for \( k \in \mathbb{Z}^d \). Again, there is considerable flexibility in these choices.

**Lemma 2.2.** For all \( \alpha, \gamma > 0 \) with \( \alpha + \gamma > d \) there exists \( C = C(\alpha, \gamma) < \infty \) so that, for all \( k \in \mathbb{Z}^d \), with \( k \neq 0 \),

\[
\sum_{l+m=k \atop l \neq 0, m \neq 0} \frac{1}{|m|^{\alpha |l|}} \leq \begin{cases} 
C (1 + |k|)^{-\beta}, & \text{if } \alpha \neq d \text{ and } \gamma \neq d, \\
C (1 + |k|)^{-\beta \log(1 + |k|)}, & \text{if } \alpha = d \text{ or } \gamma = d,
\end{cases}
\]

where \( \beta = \min\{\alpha, \gamma, \alpha + \gamma - d\} \) and the sum is over all indices \( l, m \) in \( \mathbb{Z}^d \) satisfying the given constraints.

One way to prove this lemma, whose proof is omitted, is to compare above and below by suitable continuous integrals.

2.3. **Two dimensional Navier-Stokes equations.** We briefly treat the two dimensional Navier-Stokes in its vorticity formulation, since this will be used in section 4 as an example where the comparison equation yields exact statements about the integrability of the stochastic representation.
In dimension $d = 2$ the vorticity $\xi = \text{curl} u$ is a scalar and satisfies, on the torus $[0, 2\pi)^2$ and with periodic boundary conditions,

\begin{equation}
\begin{aligned}
\partial_t \xi &- \Delta \xi + (u \cdot \nabla) \xi = f, \\
\xi(0) & = \xi^0,
\end{aligned}
\end{equation}

where $u$ is the solution to the Navier-Stokes equations. The Fourier coefficients satisfy the following system,

\[ \dot{\xi}_k = -|k|^2 \xi_k + \sum_{l+m=k} \frac{k \cdot l^\perp}{|l|^2} \xi_l \xi_m + f_k, \]

where $l^\perp = (l_2, -l_1)$. For simplicity we shall assume that $f_0 = 0$ and the vorticity has mean value $\xi_0$ zero and is omitted from the system.

We then set $\chi_k = |k|^\alpha \xi_k$ for some $\alpha > \frac{1}{2}$. For $C_b > 0$ we then define

\[ \lambda_k = |k|^2, \quad B_{k, l, m}(\chi, \chi') = \frac{k \cdot l^\perp}{|k|^2} \chi \chi', \quad q_{k, l, m} = C_b^{-1} \frac{|k|^{\alpha-2} |k \cdot l^\perp|}{|l|^{\alpha+2} |m|^{\alpha}}, \]

for all $k, l, m \in Z^2$ satisfying $k \cdot l^\perp \neq 0$ and $l + m = k$ (and zero otherwise). Lemma 2.2 ensures that $q_k < \infty$ and that $q_k \to 0$ as $|k| \to \infty$. Taking $C_b$ large enough we have that $q_k < 1$ (note that here we may take $p_k = 0$). So the recasting is complete if we define $\gamma_k = (|k|^\alpha / d_k) f_k$.

### 2.4. A surface growth equation.

The final example illustrates the change in weights needed for a higher order equation and the need to consider linear instabilities. In particular, the linear operator does not generate a diffusion. Therefore, the Fourier transform is necessary for the stochastic representation. Consider the following scalar equation arising in some models for surface growth,

\[ \partial_t u = -a_1 \Delta^2 u - a_2 \Delta u - a_3 \Delta |\nabla u|^2 + a_4 |\nabla u|^2 + f, \]

with periodic boundary conditions on $[0, 2\pi)^d$, with $d = 1, 2$ and $a_i > 0$ for $i = 1, 2, 3$. See Raible et al. [14] for the derivation of the model, and Blömker et al. [5] for a rigorous mathematical treatment using PDE techniques. For simplicity, we assume $a_4 = 0$ and that the mean value $\int u(t, x) \, dx$ is zero, allowing us to omit the coefficient $u_0$.

The equation for the Fourier coefficients is given by

\begin{equation}
\begin{aligned}
\dot{u}_k &= -a_1 |k|^4 u_k + a_2 |k|^2 u_k + a_3 |k|^2 \sum_{l+m=k} (l \cdot m) u_l u_m + f_k.
\end{aligned}
\end{equation}

We set $\chi_k = |k|^\alpha u_k$ for $\alpha > 0$, with $\alpha > \max\{d, 1 + d/2\}$, and then choose, for all $k \neq 0$,

\[ \lambda_k = a_1 |k|^4, \quad p_k = \frac{a_2}{a_1} C_f^{-1} |k|^{\alpha-2} \]

and

\[ B_{k, l, m}(\chi, \chi') = \frac{l \cdot m}{|l \cdot m|} \chi \chi', \quad q_{k, l, m} = C_b^{-1} \frac{a_3 |k|^{\alpha-2} |l \cdot m|}{a_1 |l|^{\alpha} |m|^{\alpha}}, \]
with $B_{k,l,m}$ and $q_{k,l,m}$ equal to zero if $l \cdot m = 0$ or $l + m \neq k$. Lemma 2.2 guarantees that $p_k + q_k < 1$ when $C_b, C_f$ are taken large enough and we can define $d_k = 1 - q_k - p_k$ and $\gamma_k = \frac{|k|^{a-4}}{a!d_k} f_k$ to obtain a system in the form (2.1).

2.5. **Discussion of extensions and generalisations.** We now list a number of possible extensions to the our basic system (2.1) for which modified tree representations will hold.

2.5.1. **PDEs in general domains with other boundary conditions.** If there is a complete countable set of $L^2$-eigenfunctions $(e_k)_{k \in \mathbb{N}}$ of $A$ in which to expand solutions as $u = \sum_{k=1}^{\infty} u_k e_k$, one can recast PDEs in general domains with various boundary conditions into a suitable ODE setting. This is similar to spectral Galerkin methods. Consider for instance

$$\partial_t u = Au + B(u,u)$$

for a bilinear operator $B$, and suppose that $Ae_k = \lambda_k e_k$. Then

$$\partial_t u_k = \lambda_k u_k + \sum_{m,l=1}^{\infty} \langle B(e_m,e_l), e_k \rangle_{L^2} u_m u_l.$$ 

This can easily be transformed into the general system (2.1) by choosing appropriate weights. This would cover our earlier examples, Burgers equation, Navier-Stokes or the surface growth equation, in a regular domain with, for instance, Dirichlet or Neumann boundary conditions. Note that (2.1) is now an $\mathbb{R}$-valued system posed in $\ell^{\infty}(\mathbb{R})$ which is indexed over $\mathbb{N}$ instead of $\mathbb{Z}$.

2.5.2. **Polynomial non-linearities.** More general polynomial non-linearities, or several non-linearities, lead to branching systems where particles split into a larger number of descendants. Even analytic non-linearities can be handled, with the absolute values of the power series coefficients controlling the branching probabilities. Note also that a general first order term of the form $\sum_l p_{k,l} B_{k,l}(\chi_k)$, for linear $B_{k,l}: C' \to C'$, can be thought of as a branching event with a single offspring. This kind of term arises, for example, when the original PDE contains a multiplication operator $u \mapsto f u$ for a fixed function $f$.

2.5.3. **Multiplicative forcing.** A non-linear forcing term $F(u,f)$, again with polynomial $F$, can also be recast into a branching system of ODEs. This leads, say in the quadratic case, to time dependent bilinear operators $B_{k,l,m}$ whose values depend on the forcing $\gamma_k(t)$, i.e. we obtain terms like a sum over $q_{k,l,m} B_{k,l,m}(\gamma_k, \chi_m)$ in equation (2.1).
3. The branching particle representation formula

3.1. Existence and uniqueness. The next theorem shows that there is a unique local solution to \((2.1)\) taking values in the space \(\ell^\infty(C')\) of bounded families \((a_k)_{k \in \mathbb{Z}^d}\) of elements of \(C'\), with the norm \(|a|_\infty = \sup_{k \in \mathbb{Z}^d} |a_k|\), with \(|a_k| = \sqrt{a_k \cdot a_k^*}\) the norm in \(C'\). We give a simple deterministic proof, but there is also a more probabilistic proof available (see Corollary \ref{cor:probabilistic}), in the spirit of Le Jan and Sznitman \cite{LeJanSznitman}.

**Theorem 3.1** (Unique local existence). Assume that
\[
\chi(0) \in \ell^\infty(C'), \quad \gamma \in L^\infty([0, T], \ell^\infty(C')) \quad \text{for all } T > 0.
\]
Then there exists a time \(T_0 > 0\), depending only on \(\chi(0), \gamma\), and the constants appearing in the equation, such that the mild formulation \((2.4)\) has a unique solution \(\chi \in L^\infty_{loc}([0, T_0], (C')^\mathbb{Z}^d)\).

Moreover, we have either \(T_0 = \infty\) or \(\|\chi(t)\|_\infty \to \infty\) as \(t \to T_0\). Finally, if the functions \(t \mapsto \gamma_k(t)\) are \(C^k\), then \(t \mapsto \chi_k(t)\) are \(C^{k+1}\) in time and solve equation \((2.1)\).

**Proof.** The proof is a rather standard application of the Banach fixed point theorem. Let \(B\) be a ball of radius \(R > 0\) centred at the constant function with value \(\chi(0)\), in the space \(L^\infty([0, t_*], \ell^\infty(C'))\). For \(\chi \in B\) define \(F(\chi)\) by the right-hand side of \((2.4)\). Then for \(R_0 = R + \|\chi(0)\|_\infty\),
\[
|F(\chi)(k) - \chi_k(0)| \leq \left(\|\chi(0)\|_\infty + C_f p_k R_0 + C_b q_k R_0^2 + \|\gamma(t)\|_\infty\right)(1 - e^{-\lambda k t_*}).
\]
If we choose \(R > \|\chi(0)\|_\infty + \sup \|\gamma(t)\|_\infty\) and \(t_*\) small enough we see that \(F\) maps \(B\) into itself. Here we have used assumption \((2.3)\) to control the large \(|k|\) s. Moreover, if \(\chi^1\) and \(\chi^2\) are in \(B\), then for \(t \leq t_*\),
\[
|F(\chi^1) - F(\chi^2)|_k(t) \leq (C_f p_k + 2C_b R_0 q_k)(1 - e^{-\lambda k t_*}) \sup_{t \leq t_*} \|\chi^1(t) - \chi^2(t)\|_\infty.
\]
Hence \(F\) is a strict contraction in \(L^\infty([0, t_*], \ell^\infty(C'))\) if we choose \(t_*\) small enough. Here we need again, for large \(|k|\), the assumption \((2.3)\).

The assertion for the time \(T_0\) follows in a standard manner by gluing together local solutions. The continuity of \(t \mapsto \chi_k(t)\) follows from the mild form \((2.4)\). It is even differentiable with bounded derivative. The \(C^k\)-regularity follows by differentiating \((2.4)\) and the higher regularity follows from differentiating \((2.1)\). \(\square\)

A simple global existence result can be proved under the assumptions of linear stability and small data.

**Proposition 3.2** (Global existence for small data). Under the assumptions of Theorem \ref{thm:unique}, assume that there exists \(\delta > 0\) so that
\[
d_k |\gamma_k| < \delta(1 - C_f p_k) - C_b \delta^2 q_k, \quad \text{for all } k \in \mathbb{Z}^d.
\]
Then for each initial condition \(\|\chi(0)\|_\infty \leq \delta\), there is a global solution \(\chi\) to equations \((2.1)\) satisfying \(\sup_{t \geq 0} \|\chi(t)\|_\infty \leq \delta\).
Proof. Let \( v_k(t) = |\chi_k(t)| \). When \( v_k(t) \neq 0 \) and \( v_k(t) \leq \delta \) for all \( \lambda \in \mathbb{Z}^d \) one has the estimate
\[
\partial_t v_k \leq -\lambda_k \left( 1 - C_f p_k \right) v_k + \lambda_k \left( C_p q_k \delta^2 + d_k |\gamma_k| \right).
\]
The assumption implies that the right hand side of (3.1) is negative when \( v_k = \delta \) and global existence follows from a comparison argument for one-dimensional ODEs.

3.2. The branching tree. We now give a construction of the branching process that will be used to represent the solutions of (2.1). We will label particles of the process with labels taken from the set \( \mathcal{F} = \bigcup_{n=0}^{\infty} \{0, 1, 2\}^n \).

The history of a particle \( \alpha = (\alpha_1, \ldots, \alpha_n) \) can be read off by interpreting \( \alpha_j = 0 \) as the flip at generation \( j \), and \( \alpha_j = 1 \) (or 2) as being child 1 (or 2) in a binary branching event at generation \( j \).

For \( \alpha \in \{0, 1, 2\}^n \) we write \( |\alpha| = n \) which we call the length of the label. We write \( \alpha = \emptyset \) for the single label of length zero. When \( \alpha = (\alpha_1, \ldots, \alpha_n) \) we write \( \alpha_j \) for the label \( \alpha_j = (\alpha_1, \ldots, \alpha_j) \) of its ancestor at generation \( j \in \{0, 1, \ldots, n-1\} \) (and set \( \alpha_0 = \emptyset \)). For \( i \in \{0, 1, 2\} \) we write \( (i, \alpha) \) for the label \( (i, \alpha_1, \ldots, \alpha_n) \) and \( (\alpha, i) \) for the label \( (\alpha_1, \ldots, \alpha_n, i) \) (or \( (i, \alpha) = (\alpha, i) = (i) \) if \( \alpha = \emptyset \)).

We construct the branching particle sys-
define birth and death times
\[ \tau^B_\alpha = \tau^D_\alpha | n, \quad \tau^D_\alpha = \tau^B_\alpha + \hat{\lambda}^{-1} \hat{E}_\alpha, \]
and the particle positions
\[ \hat{K}_\alpha = \begin{cases} \hat{K}_\alpha | n, & \alpha_{n+1} = 0, \\ Y_\alpha^{(1)}(\hat{K}_\alpha | n), & \alpha_{n+1} = 1, \\ Y_\alpha^{(2)}(\hat{K}_\alpha | n), & \alpha_{n+1} = 2. \end{cases} \]
This defines a complete tree of all possible branching and flipping particles rooted at \( k \). In the desired evolution the particles will choose whether to flip, branch or die according to the probabilities \( p_k, q_k, d_k \).

![Figure 2. The construction of the tree. At each event time \( \tau \), there is a random selection between either death, flip or branch of two new particles to states \( l \) and \( m \) (depending on the state \( k \) of the parent particle).](image)

We now define indicator variables \( (I_\alpha)_{\alpha \in \mathcal{F}} \) to decide whether a particular branch has survived. Define \( I_\emptyset = 1 \) and, for \( \alpha \) of length \( n + 1 \),
\[ I_\alpha = \begin{cases} 1 & \text{if } \alpha_{n+1} = 0 \text{ and } U_\alpha \in [0, p_{\hat{K}_{\alpha | n}}], \\ 1 & \text{if } \alpha_{n+1} \in \{1, 2\} \text{ and } U_\alpha \in [1 - q_{\hat{K}_{\alpha | n}}, 1], \\ 0 & \text{otherwise}. \end{cases} \]

Fix an isolated cemetery state \( \Delta \) and define, for \( |\alpha| = n \),
\[ K_\alpha = \begin{cases} \hat{K}_\alpha & \text{if } \prod_{j=1}^n I_{\alpha | j} = 1, \\ \Delta & \text{otherwise}. \end{cases} \]
The collection \( \mathcal{T}_k = (K_\alpha, \tau^B_\alpha, \tau^D_\alpha)_{\alpha \in \mathcal{F}} \) now defines our branching tree rooted at \( k \). It lives in the space defined by
\[ \mathcal{T} = \left( (Z^d \cup \{\Delta\}) \times [0, \infty) \times [0, \infty) \right)^\mathcal{F}. \]
We denote the law of \( \mathcal{T}_k \) on \( \mathcal{T} \) by \( P_k \).

The descendants of any one particle in the tree form a new tree. To make this precise we define shift maps \( \pi_i : \mathcal{T} \to \mathcal{T} \), for \( i = 0, 1, 2 \) as follows. For
Lemma 3.3. Let $T_k = (K_0, \tau^D_0, \tau^R_0)_{\alpha \in \mathcal{F}}$ have law $P_k$. Then

1. conditional on $\{\tau^D_0 \in ds, K_0 = k\}$ the tree $\pi_0(T_k)$ has the law $P_k$.
2. conditional on $\{\tau^D_0 \in ds, K_{(1)} = m, K_{(2)} = 1\}$ the trees $\pi_1(T_k)$ and $\pi_2(T_k)$ are independent and have laws $P_m$ and $P_1$.

We want to ensure that the tree has only finitely many branches before time $t$. Define $N_{[0,t]} : \mathcal{F} \to \mathbb{N}$ by $N_{[0,t]}(t) = |\{\alpha \in \mathcal{F} : s_\alpha \leq t\}|$, that is, the cardinality of the set of particles born before time $t$.

Lemma 3.4. Under $P_k$ the variables $N_{[0,t]}$ are almost surely finite for all $t \geq 0$.

Proof. Let $P_k(t) = P_k[N_{[0,t]} < \infty]$. By conditioning on the values of $\tau^D_0$, $K_0$, $K_{(1)}$, $K_{(2)}$ and using Lemma 3.3

$$P_k(t) = e^{-\lambda_k t} + \int_0^t \lambda_k e^{-\lambda_k (t-s)} \left[ p_k P_k(t) + \sum_{l,m \in \mathbb{Z}^d} q_{k,l,m} P_l(s) P_m(s) + d_k \right] ds.$$

Hence, $(P_k(t) : k \in \mathbb{Z}^d, t \geq 0)$ is a bounded, real-valued solution to the equation (2.1) with forcing $\gamma \equiv 1$ and bilinear operators $B_{k,l,m}(\chi, \chi') = \chi \chi'$. By Theorem 3.1 there is only one solution, namely $P_k(t) = 1$ for all $k, t$. \hfill \square

A simple criterion that ensures that the branching process becomes extinct with probability one, that is $K_\alpha = \Delta$ for all large $|\alpha|$, is that

$$q_k \leq d_k \quad \text{and} \quad p_k < 1 \quad \text{for all} \quad k \in \mathbb{Z}^d.$$  \hfill (3.2)  

Indeed the number of particles alive at time $t$ is an integer valued process whose successive values, under the condition (3.2), form a sub-critical branching process. Therefore it eventually reaches zero. The number of values $k \in \mathbb{Z}^d$ taken by particles before this extinction is almost surely finite. The conditions that $\lambda_k > 0$ and $p_k < 1$ ensure that the extinction time for the branching particle system is almost surely finite. Note that, as explained in Remark 2.1, we can always choose the system (2.1) in such a way that (3.2) holds.

3.3. The evaluation along the tree. We now fix a forcing functions $\gamma$ and an initial condition $\chi(0)$. We wish to define evaluation maps $R_t : \mathcal{F} \to \mathbb{C}^r$ for $t \geq 0$, which will depend on $\gamma$ and $\chi(0)$. These will satisfy a recursive property that allows them to be calculated backwards along the tree.
For the sake of simplicity, we introduce the following abbreviations: given a branching tree $T = (k_\alpha, s_\alpha, t_\alpha)_{\alpha \in \mathcal{S}}$ and a particle labelled $\alpha \in \mathcal{S}$, with $k_\alpha \neq \Delta$, we say that the particle has a
d
definition: if $k_{\alpha,0} = k_{\alpha,1} = k_{\alpha,2} = \Delta$, 
flip: if $k_{\alpha,0} \neq \Delta$ and $k_{\alpha,1}, k_{\alpha,2} = \Delta$, 
branch: if $k_{\alpha,0} = \Delta$ and $k_{\alpha,1}, k_{\alpha,2} \neq \Delta$.

Under each probability $P_k$, every particle $\alpha$ for which $K_\alpha \neq \Delta$ must do exactly one of the above three possibilities.

Lemma 3.5. There exist a family of maps $R_t : \mathcal{T} \to \mathcal{C}^r$, for $t \geq 0$, satisfying, when $N_{[0,t]}(T) < \infty$, the implicit formula

\begin{equation}
R_t(T) = \begin{cases} 
\chi_{k_0}(0) & t_0 \geq t, \\
\gamma_{k_0}(t - t_0) & t_0 < t, \text{ death at } 0, \\
C_f R_{t-t_0}(\pi_0(T)) & t_0 < t, \text{ flip at } 0, \\
C_b B_{k_0,k_1,k_2} \left( R_{t-t_0}(\pi_1(T)), R_{t-t_0}(\pi_2(T)) \right) & t_0 < t, \text{ branch at } 0.
\end{cases}
\end{equation}

Proof. Informally, since the tree is finite when $N_{[0,t]} < \infty$ the value of $R_t(T)$ can be calculated backwards along the tree, starting at time $s = t$ and working back to time $s = 0$: evaluate the initial condition $\chi(0)$ at any particles that are alive at time $t$, evaluate the forcing function $\gamma(s)$ at any particle that dies at time $s < t$, and apply the bilinear operators at the times of branching events.

For a careful proof one can define a sequence of approximations $R_n(T)$ in the following way:

\begin{equation}
R_n(T) = \begin{cases} 
\chi_{k_0}(0) & t_0 \geq t, \\
\gamma_{k_0}(t - t_0) & t_0 < t, \text{ death at } 0, \\
1 & \text{ otherwise},
\end{cases}
\end{equation}

and $R_{n+1}(T)$ is given by

\begin{equation}
R_{n+1}(T) = \begin{cases} 
\chi_{k_0}(0) & t_0 \geq t, \\
\gamma_{k_0}(t - t_0) & t_0 < t, \text{ death at } 0 \\
C_f R_{n,t-t_0}(\pi_0(T)) & t_0 < t, \text{ flip at } 0 \\
C_b B_{k_0,k_1,k_2} \left( R_{n,t-t_0}(\pi_1(T)), R_{n,t-t_0}(\pi_2(T)) \right) & t_0 < t, \text{ branch at } 0.
\end{cases}
\end{equation}

If $N_{[0,t]} < \infty$ then only finitely many iterations are needed and $R_n(T) = R_{n,T}(T)$ for all large $n$. \hfill \Box

In some cases the evaluation can be written more explicitly. Let $F(t)$ (respectively $B(t)$) be the number of particles that have flipped (respectively branched) before time $t$. Let $D(t)$ be the set of labels of particles that have died strictly before time $t$.

Consider the special case where $r = 1$ and that all the bilinear forms $B_{k_0,k_1,k_2}$ coincide with the usual product in $C$. Then the evaluation is given, almost
In the general case, we can only verify, under $P_k$, that
\begin{equation}
R_t(T) = C_b \left( C_f^B(t) \prod_{\alpha \in D(t)} \gamma_{k\alpha}(t-t\alpha) \prod_{\alpha \in [r\alpha,t\alpha)} \chi_{k\alpha}(0) \right).
\end{equation}

In the general case, we can only verify, under $P_k$, that
\begin{equation}
|R_t(T)| \leq C_b \left( C_f^B(t) \prod_{\alpha \in D(t)} |\gamma_{k\alpha}(t-t\alpha)| \prod_{\alpha \in [r\alpha,t\alpha)} |\chi_{k\alpha}(0)| \right),
\end{equation}
and that equality holds in (3.6) if $|B_{k,1,m}(\chi,\chi')| = |\chi||\chi'|$ for all $k, l, m$ and $\chi, \chi'$.

3.4. The representation formula. Consider an initial condition $\chi(0) \in \ell^\infty(C^r)$, and a forcing $\gamma \in L^\infty([0,T], \ell^\infty(C^r))$. The representation formula for solutions of (2.1), when the expectation exists, is given by
\begin{equation}
\chi_k(t) = E_k[R_t], \quad k \in Z^d.
\end{equation}

**Theorem 3.6.** Suppose that there exists $C = C(\gamma, \chi(0), T) < \infty$ so that
\begin{equation}
E_k|R_t| \leq C \quad \text{for all } k \in Z^d \text{ and all } t \in [0,T].
\end{equation}

Then $\chi$ defined in (3.7) is the unique $L^\infty([0,T], \ell^\infty(C^r))$ solution of problem (2.1) for the data $\gamma, \chi(0)$.

**Proof.** Note that uniqueness follows from Theorem 3.1. Fix a $k \in Z^d$. Conditioning on the values of $\tau_0, K(0), K(1), K(2)$ and using lemma 3.3 leads immediately to the mild form of the equation (2.4). The uniform (over $k$) integrability is necessary to show that the sum over $l, m$ converges.

In the next two sections we discuss how to check the integrability assumption and what to do if it fails. We also see, what happens if the solution fails to be in $\ell^\infty$.

4. The comparison equation

4.1. The comparison equation. The comparison equation for system (2.1) is formed by taking the norm of the data $|\chi_k(0)|$ and $|\gamma_k|$ as new data for the system
\begin{equation}
\begin{cases}
\dot{\tilde{\chi}}_k = \lambda_k \left[ -\tilde{\chi}_k + C_f P_k \tilde{\chi}_k + C_b \sum_{l,m \in Z^d} q_{k,l,m} \tilde{\chi}_l \tilde{\chi}_m + d_k |\chi_k| \right], \\
\tilde{\chi}_k(0) = |\chi_k(0)| \quad \text{for } k \in Z^d.
\end{cases}
\end{equation}

We now look for non-negative real solutions $\tilde{\chi}_k(t)$.

We also define a modified evaluation operator $\tilde{R}_t$ on $T$ by the implicit formula (3.3) where we use the new data $|\chi_k(0)|$ and $|\gamma_k|$ and the bilinear operators are replaced by $B_{k,1,m}(\chi, \chi') = \chi \chi'$, the normal product of real numbers. Then $\tilde{R}_t(T) \geq 0$ and formally we expect that
\begin{equation}
\tilde{\chi}_k(t) = E_k[\tilde{R}_t], \quad k \in Z^d
\end{equation}
should solve the comparison equation.
The next theorem confirms this and shows that a finite solution to the comparison equation (4.1) is a sufficient, and sometimes necessary, condition for the tree expectations $E_k[R_t]$ to exist.

**Theorem 4.1.** If the expectations in (4.2) are finite for all $t \in [0, T]$ and $k \in \mathbb{Z}^d$, then they define a mild solution to the comparison equation (4.1) for which $t \mapsto \tilde{\chi}_k(t)$ is continuous on $[0, T]$.

Conversely if there exists a finite mild solution of (4.1), that is, $\tilde{\chi}_k(t) < \infty$ for $t \in [0, T]$ and $k \in \mathbb{Z}^d$, then the expectations in (4.2) are finite for $t \in [0, T]$, and they define the smallest positive solution of (4.1).

Finally, the comparison $E_k[R_t] \leq E_k[\tilde{R}_t]$ holds, with equality whenever $|B_{k,l,m}(\chi, \chi')| = |\chi||\chi'|$ for all $k, l, m$ and $\chi, \chi'$.

**Proof.** For the first claim of the theorem, condition on the values of $\tau^D_0, K_{(0)}, K_{(1)}, K_{(2)}$, and apply Lemma 3.3 to see that the expectations $\tilde{\chi}_k(t) = E_k[\tilde{R}_t]$ satisfy the mild form of the comparison equation. Moreover the mild form of the equation shows that $e^{k(t)} \tilde{\chi}_k(t)$ is continuous and increasing in $t$. Note that the convergence of the series in the mild formulation is not a problem here, because due to positivity, we can use monotone convergence.

For the second part of the theorem, let $\chi$ be a mild solution of the comparison equation (4.1) in $[0, T]$ with data $|\chi_k(0)|$ and $|\gamma_k|$. Define a sequence of evaluations on the trees as follows: set $\tilde{R}^{(expl)}_{n,t}(T, \tilde{\chi}) = \tilde{\chi}_{k_0}(t)$ and for each $n \geq 0$,

$$R^{(expl)}_{n+1,t}(T, \tilde{\chi}) = \begin{cases} 
|\chi_{k_0}(0)| & t_0 \geq t, \\
|\gamma_0(t-t_0)| & t_0 < t, \text{ death at } 0, \\
C_f R^{(expl)}_{n,t-t_0}(\pi_0(T), \tilde{\chi}) & t_0 < t, \text{ flip at } 0, \\
C_b R^{(expl)}_{n,t-t_0}(\pi_1(T), \tilde{\chi}) R^{(expl)}_{n,t-t_0}(\pi_2(T), \tilde{\chi}) & t_0 < t, \text{ branch at } 0.
\end{cases}$$

(In the language of next section, the evaluation $R^{(expl)}_{n,t}$ correspond to a pruning of the tree after $n$ generations and the expectation $E_k[R^{(expl)}_{n,t}(T, \tilde{\chi})]$ will solve a Picard iteration scheme for (4.1)).

Note that, upon dying, flipping or branching, particles of length $n$ are evaluated using the true solution $\tilde{\chi}$. Inductively one checks, by conditioning on the first event, that for all $n \geq 0$

$$E_k[R^{(expl)}_{n,T}(T, \tilde{\chi})] = \tilde{\chi}_k(t).$$

Since $N_{[0,t]} < \infty$ under $P_k$ we have that $R^{(expl)}_{n,T}(T) \to \tilde{R}_t(T)$ almost surely. By Fatou’s lemma and (4.4) we find that $E_k[\tilde{R}_t] \leq \tilde{\chi}_k(t) < \infty$.

The third claim of the theorem is immediate from the upper bound (3.6) and the fact that it is an equality under the conditions given.

**Remark 4.2.** Note that in the above theorem, and its corollary below, we do not insist the solutions are bounded in $\ell^\infty$.

The first two parts of the above theorem show that, when there exists a finite mild solution $\tilde{\chi}$ to (4.1), the function defined by $E_k[\tilde{R}_t]$ is the smallest
solution to (4.1) lying below $\tilde{\chi}$. Note in the case of $\ell^\infty$ solutions there is uniqueness of solutions, as in Theorem 3.1.

As in Le Jan and Sznitman [8], it is possible, when there exists a finite mild solution $\tilde{\chi}$ to (4.1), to show that $n \to \bar{R}_{n,t}^{(\text{expl})}(T, \tilde{\chi})$ is a non-negative martingale (with respect to a natural filtration along generations of the tree). Uniform integrability of this martingale would then imply that $\tilde{\chi}_k(t) = E_k[\tilde{R}_t]$.

**Corollary 4.3.** Under the conditions of either the first or the second part of theorem 4.1, the expectations $\chi_k(t) = E_k[R_t]$ are well defined for $t \in [0, T]$ and $k \in \mathbb{Z}^d$ and form a mild solution to (2.1). Moreover, such a solution is unique among all mild solutions $\chi'$ such that

$$\chi'_k(t) \leq E_k[\tilde{R}_t], \quad \text{for all } k \in \mathbb{Z}^d, \ t \in [0, T].$$

**Proof.** The expectations $E_k[R_t]$ are well defined by theorem 4.1 as $|R_t| \leq \bar{R}_t$. By conditioning on the first event as before they will solve the mild equation. Note that in this case the convergence of the sums in the mild equation is guaranteed by the finiteness of the comparison equation.

Let $\chi'$ be a mild solution verifying (4.3) and define a sequence of evaluations $R_{n,t}^{(\text{expl})}(T, \chi')$ for $n \in \mathbb{N}$ as in the proof of previous theorem, that is $R_{0,t}^{(\text{expl})}(T) = \chi'_{k_0}(t)$ and, for all $n \geq 1$, $R_{n,t}^{(\text{expl})}(T)$ is defined as in formula (4.3) with data $\chi'$ and $\gamma$ and with products $B_{k,k_1,k_2}$ in the place of usual product.

By assumption (4.5) and an argument similar to (3.6) it follows that

$$|R_{n,t}^{(\text{expl})}(T, \chi')| \leq \bar{R}_{n,t}^{(\text{expl})}(T, \tilde{\chi}),$$

where $\tilde{\chi}_k(t) = E_k[\tilde{R}_t]$ and $R_{n,t}^{(\text{expl})}(T, \tilde{\chi})$ are taken from the proof of Theorem 4.1. Moreover, as in that proof, we can show inductively that $\chi'_k(t) = E_k[R_{n,t}^{(\text{expl})}(T, \chi')]$.

We next note that $R_{n,t}^{(\text{expl})}(T, \chi') = R_t(T)$ and $\bar{R}_{n,t}^{(\text{expl})}(T, \tilde{\chi}) = \bar{R}_t(T)$ on the set $\Omega_{n,t} = \{N_{[0,t]}(T) \leq n\}$. Thus,

$$E_k[R_{n,t}^{(\text{expl})}(T, \tilde{\chi})1_{\Omega_{n,t}}] = \tilde{\chi}_k(t) - E_k[R_{n,t}^{(\text{expl})}(T, \chi')1_{\Omega_{n,t}}] = E_k[\tilde{R}_t] - E_k[\tilde{R}_t1_{\Omega_{n,t}}] = E_k[\tilde{R}_t1_{\Omega_{n,t}}],$$

and therefore

$$|\chi'_k(t) - E_k[R_t]| \leq E_k[R_{n,t}^{(\text{expl})}(T, \chi') - R_t] = E_k[R_{n,t}^{(\text{expl})}(T, \chi') - R_t1_{\Omega_{n,t}}],$$

$$\leq E_k[(\bar{R}_{n,t}^{(\text{expl})}(T, \tilde{\chi}) + \tilde{R}_t)1_{\Omega_{n,t}}] = 2E_k[\tilde{R}_t1_{\Omega_{n,t}}].$$

Letting $n \to \infty$ we conclude that $\chi' = \chi$, the solution given by the probabilistic representation. □

### 4.2. Examples.

We can remove the weights used to cast the equation into our abstract form and rewrite the comparison equation as equations for the Fourier coefficients of a scalar PDE.
Consider the Burgers equation example discussed in section 2.5. Defining \( \tilde{u}_k = w_k^{-1} \tilde{\chi}_k \) we obtain a comparison equation of the form

\[
\dot{\tilde{u}}_k = -|k|^2 \tilde{u}_k + \sum_{l+m=k} |m| \tilde{u}_m + |f_k|.
\]

which in the space coordinates corresponds to the scalar equation

\[
\partial_t \tilde{u} = \Delta \tilde{u} + \tilde{u} (-\Delta)^{\frac{1}{2}} \tilde{u} + \tilde{f}
\]

where \( \tilde{f} \) has Fourier coefficients \( |f_k| \). Note that this scalar comparison equation is independent of the choice of weights (called \textit{majorizing kernels} in Bhattacharya et al. [3]).

For the two-dimensional Navier Stokes equation discussed in section 2.3, the comparison equation for \( \tilde{\xi}_k = |k|^{-\alpha} \tilde{\chi}_k \) takes the form

\[
\dot{\tilde{\xi}}_k = -|k|^2 \tilde{\xi}_k + \sum_{l+m=k} \frac{|k \cdot l|}{|l|^2} \tilde{\xi}_l \tilde{\xi}_m + |f_k|,
\]

which does not have a nice expression in the space variables.

For the surface equations discussed in section 2.4, the comparison equation becomes

\[
\partial_t \tilde{u} = -a_1 \Delta^2 \tilde{u} - a_2 \Delta \tilde{u} - \Delta(-\Delta)^{\frac{1}{2}} \tilde{u}^2 + \tilde{f},
\]

where the forcing \( \tilde{f} \) has Fourier coefficients \( |f_k| \).

Whenever there is a solution to these scalar comparison equations with finite Fourier coefficients we obtain the existence of mild solutions to the corresponding abstract ODEs given by the stochastic representation (3.7). This in turn is equivalent to the existence of solutions to the original PDEs with finite Fourier coefficients.

However all three scalar comparison equations have quadratic growth and it is possible to show, for example for zero forcing and large enough initial data, that the solutions explode in finite time. See for example [10] and the references therein for the case of branching with diffusion.

\textbf{Remark 4.4.} In the case of the 2d Navier Stokes, the 1d Burgers, or the surface equation, the equality in the last part of Theorem 4.1 holds. This implies that the stochastic representation \( E_k[R_t] \) is well defined as the expectation of an integrable variable, if and only if the corresponding comparison equation has a solution with finite Fourier coefficients. In particular, for any suitable weight, the representation will fail to exist at the same time, once a Fourier mode in the comparison equation becomes infinite for all solutions.

5. THE PRUNED APPROXIMATION

5.1. \textbf{An ODE example of the approximation scheme.} We first explain the main ideas of the approximation scheme on a simple example, namely the
A BRANCHING PROCESS REPRESENTATION... 17

The solution can be given by the stochastic representation $u(t) = E[u(0)^{N_t}]$, where $N_t$ is the number of particles at time $t$ of a simple rate one branching process starting from a single particle at time 0. It’s easy to verify that the representation is well defined for all time $t \geq 0$ if and only if $u(0) \leq 1$, in that the variable $|u(0)|^{N_t}$ becomes non-integrable for large $t$ when $|u(0)| > 1$, while the solutions of the equation blow up only if $u(0) > 1$.

We now give a modification of the branching process. Give each particle a label from the integers $\mathbb{N}$. Particles still branch at rate 1 but a particle with label $n$ produces two offspring, one with label $n$ and one with label $n - 1$. When a particle of type 0 tries to branch it simply dies. Start with a single particle with label $n$ and let $N_t(n)$ denote the number of particles at time $t$. Set $u_n(t) = E[u(0)^{N_t(n)}]$ for $n \geq 0$ and $u_{-1} \equiv 0$. Then $u_n(t)$ solves the following semi-implicit iterative scheme

$$\dot{u}_n = -u_n + u_{n-1}u_n, \quad u_n(0) = u(0), \quad \text{for } n \geq 0.$$ 

It is straightforward to check that $u_n(t)$ is well defined for all $n$ and $t$. Moreover, $u_n$ converges to the solution $u(t)$ of the original problem for each initial condition $u(0) \leq 1$. This yields the stochastic representation

$$u(t) = \lim_{n \to \infty} E[u(0)^{N_t(n)}]$$

valid for all $u(0) \leq 1$ and all $t \geq 0$.

**Remark 5.1.** The seemingly simpler modification (used by Le Jan and Sznitman [3] for their uniqueness proof and by Bhattacharya et al. [3]) where a particle with label $n$ produces two offspring each with label $n - 1$, leads to the explicit iterative scheme $\dot{u}_n = -u_n + u_{n-1}^2$. Unfortunately, the limit of $u_n(t)$ for large $t$, as $n \to \infty$, fails to exist for $u(0) < -1$.

The semi-implicit approximation scheme works for other polynomial non-linearities. For example, if one considers $\dot{u} = -u - u^3$, the approximation scheme $u_n = -u_n + u_{n-1}^3u_n$, where each particle with label $n$ branches into three particles, one with label $n$ and two with label $n - 1$, is convergent to the true global solution for any initial condition.

5.2. **A general approximation scheme.** The aim is to define a sequence of approximations $\chi_k^n(t)$ to our abstract system of ODEs (2.1). These approximations will have a stochastic representation without any integrability problems.

Rather than construct a particle system with labelled particles as described in the previous section, we put the modification into the evaluation operators. We claim there exists a sequence of evaluation operators $R_{n,t} : \mathcal{T} \to \mathcal{C}^r$ satisfying the following implicit relations on $N_{[0,t]} < \infty$:

$$R_{0,t}(\mathcal{T}) = \begin{cases} 
\chi_{k_0}(0) & \text{if } t_0 \geq t, \\
0 & \text{otherwise}
\end{cases}$$
and, for $n \geq 1$, $R_{n,t}(\mathcal{T})$ equals

\begin{equation}
(5.1)
\begin{cases}
\chi_{k_0}(0) & t_0 \geq t, \\
\gamma_{k_0}(t-t_0) & t_0 < t, \text{ death at } \emptyset, \\
C_f R_{n,t-t_0}(\pi_0(\mathcal{T})) & t_0 < t, \text{ flip at } \emptyset, \\
C_b B_{k_0,k(1),k(2)}(R_{n,t-t_0}(\pi_1(\mathcal{T})),R_{n-1,t-t_0}(\pi_2(\mathcal{T}))) & t_0 < t \text{ branch at } \emptyset.
\end{cases}
\end{equation}

The existence of $R_{n,t}$ can be established exactly as in Lemma 3.3. The intuitive link with the labelled particle picture in the last section is that $R_{n,t}(\mathcal{T})$ corresponds to the evaluation operator applied to the tree started at a particle with label $n$ at position $k$.

The implicit relation implies that if $N_{[0,t]} \leq m$ then $R_{n,t}(\mathcal{T}) = R_{t}(\mathcal{T})$ whenever $n \geq m$. Moreover when $R_{n,t}(\mathcal{T}) \neq R_{t}(\mathcal{T})$ then $R_{n,t}(\mathcal{T}) = 0$. Thus there exist increasing sets $\Omega_{n,t} \subset \mathcal{F}$ so that

\begin{equation}
(5.2)
R_{n,t}(\mathcal{T}_k) = R_{t}(\mathcal{T}_k) \mathbf{1}_{\Omega_{n,t}} \quad \text{and} \quad \{N_{[0,t]} < \infty\} \subseteq \bigcup_n \Omega_{n,t}.
\end{equation}

We now define the stochastic representation using these modified evaluations by

\begin{equation}
(5.3)
\chi_k^{(n)}(t) = E_k[R_{n,t}].
\end{equation}

The fact that this expectation is always well defined is part of the following result.

**Proposition 5.2.** Suppose that $\chi(0) \in \ell^\infty(\mathbf{C}')$ and $\gamma \in L^\infty([0,T],\ell^\infty(\mathbf{C}'))$. Then the expectations in (5.3) are well defined and $\chi_k^{(n)}(t)$ are the unique
\(L^\infty([0, T], \ell^\infty(C'))\) mild solution to the following approximation scheme

\[(5.4)\]
\[
\dot{\chi}_k^{(n)} = -\lambda_k \chi_k^{(n)} - C_f p_k \chi_k^{(n)} + C_b \sum_{l,m \in \mathbb{Z}^d} q_{k,l,m} B_{k,l,m} (\chi_l^{(n)}; \chi_m^{(n-1)}) + d_k \gamma_k,
\]

with initial condition \(\chi_k^{(n)}(0) = \chi_k(0)\) for all \(k \in \mathbb{Z}^d\) and \(n \in \mathbb{N}\).

**Proof.** The local existence and uniqueness of solutions for the approximation scheme, follows from the same methods as in the proof of Theorem 3.1 plus an inductive argument in \(n \geq 0\). The fact that solutions are globally defined follows, again by induction, from the simple estimate

\[
|\chi_k^{(n)}(t)| \leq \|\chi(0)\|_\infty + \sup_{t \in [0,T]} \|\gamma\|_\infty + \lambda_k \int_0^t e^{-\lambda_k (t-s)} \left(C_f + C_b \|\chi^{(n-1)}\|_\infty\right) \|\chi^{(n)}\|_\infty ds,
\]

which, using induction and Gronwall’s lemma, easily gives boundedness of \(\|\chi^{(n)}\|_\infty\) in each interval \([0, T]\).

In order to prove that the stochastic representation (5.3) is well defined, we use a comparison argument, as in Section 4. The comparison equation for the approximation scheme is given by

\[
\dot{\tilde{\chi}}_k^{(n)} = \lambda_k \left[-\tilde{\chi}_k^{(n)} + p_k C_f \chi_k^{(n)} + C_b \sum_{l,m \in \mathbb{Z}^d} q_{k,l,m} \tilde{\chi}_l^{(n)} \chi_m^{(n-1)} + d_k |\gamma_k|\right]
\]

and the evaluation \(E_k |R_{n,t}|\) is finite as long as the \(\tilde{\chi}_k\) are finite. But this follows by the same arguments as in first part of this proof. Again \(E_k |R_{n,t}| \leq \tilde{\chi}_k \leq C\) for all \(k \in \mathbb{Z}^d\) and all \(t \in [0,T]\) with constant \(C\) depending only on \(T, \chi(0), \) and \(\gamma\).

Finally, the expectations \(E_k [R_{n,t}]\) do form the unique solution to the approximation scheme by conditioning on the first branch of the tree as in Theorem 3.6.

In the integrable case, that is where \(E_k |R_t| < \infty\), we have immediately from (5.2) that

\[
\lim_{n \to \infty} E_k [R_{n,t}] = E_k [R_t].
\]

In particular, when the expectations \(E_k [R_t]\) are bounded over \(t \in [0, T]\) and \(k \in \mathbb{Z}^d\) this implies the solutions of the approximation scheme converge to those of the original system (2.1). Our interest, however, is in the non-integrable case and we aim to show that convergence of the approximation scheme directly and deduce that the limit \(\lim_{n \to \infty} E_k [R_{n,t}]\) exists and defines a stochastic representation for all times \(t > 0\).
5.3. Global convergence of the stochastic approximation. The aim of this section is to give a few details of one example where the approximation scheme defined by the pruned representation converges, even when the direct stochastic representation fails to be integrable. In contrast to the previous section, we use PDE methods. The convergence depends crucially on the equation and how the pruning is done, as not all approximation schemes will converge globally.

For simplicity we work with the one dimensional Burgers equation with forcing (2.5). In Subsection 2.2 we recast the equation into our abstract form by considering the weighted Fourier coefficients

$$\chi_k(t) = w_k u_k(t)$$

where, as in section 2.2, the weights are given by $w_k = (1 + |k|^\alpha)$ for some $\alpha > 1$. If we assume the Fourier coefficients of the initial condition satisfy

$$\sup_k |u_k(0)| w_k < \infty$$

and the forcing function $f$ satisfies

$$\sup_k \sup_{t \in [0,T]} |f_k(t)| w_k < \infty,$$

for all $T > 0$,

then proposition 5.2 implies there is a unique global solution $\chi^{(n)}_k(t)$, given by (5.3), to the approximation equations (5.4).

**Theorem 5.3.** Assume, in addition to (5.5) and (5.6), that $u(0) \in H^1$ and $f \in L^\infty_{\text{loc}}([0,\infty), L^\infty)$. Consider the pruned approximation of the previous section. Then the limit

$$\chi_k(t) = \lim_{n \to \infty} \chi^{(n)}_k(t) = \lim_{n \to \infty} E_k [R_{n,t}]$$

exists for all $t \geq 0$ and all $k \in \mathbb{Z}$ and defines a global solution of the Fourier-transformed Burgers equation.

**Proof.** Define

$$u^{(n)}_k(t) = w_k^{-1} \chi^{(n)}_k(t).$$

Since $\chi^{(n)}$ is bounded we may reconstruct from these coefficients the function

$$u^{(n)}(t) = \sum_{k \in \mathbb{Z}} u^{(n)}_k(t) e^{ikx}.$$ 

Using the representation of Proposition 5.2, we see that, on the level of PDEs, $u^{(n)}$ solves the approximation scheme given by

$$\begin{cases}
\partial_t u^{(0)} = \partial_x^2 u^{(0)}, \\
\partial_t u^{(n)} = \partial_x^2 u^{(n)} + \partial_x u^{(n)} u^{(n-1)} + f, \\
u^{(n)}(0) = u(0).
\end{cases}$$
Fix $T > 0$ and set $C(f, T) = \sup_{t \in [0, T]} \|f(t)\|_{L^\infty}$. We first use a maximum principle argument to show
\begin{equation}
(5.8) \quad \sup_{t \in [0, T]} \|u^{(n)}(t)\|_{L^\infty} \leq \|u(0)\|_{L^\infty} + C(f, T) T \quad \text{for all } n \in \mathbb{N}.
\end{equation}

We now derive an a priori estimate for the solution. The following calculation applies to sufficiently smooth functions and standard approximation techniques imply that the resulting bound holds for the solutions above. Using (5.8), we find
\[
\frac{1}{2} \frac{d}{dt} \|\partial_x u^{(n)}\|_{L^2}^2 = -\|\partial^2_x u^{(n)}\|_{L^2}^2 - \int_0^{2\pi} \partial_x u^{(n)} u^{(n-1)} \partial^2_x u^{(n)} dx \\
- \int_0^{2\pi} \partial^2_x u^{(n)} f dx \\
\leq -\|\partial^2_x u^{(n)}\|_{L^2}^2 + C \|\partial^2_x u^{(n)}\|_{L^2}^{3/2} + C \|\partial^2_x u^{(n)}\|_{L^2},
\]
where we have used the Poincaré and Cauchy-Schwartz inequalities. Note that the constant $C > 0$ depends only on $T, C(f, T)$, and $u(0)$. Thus we find another constant, also denoted $C$, such that for all $n \in \mathbb{N}$
\[
\sup_{t \in [0, T]} \|u^{(n)}(t)\|_{L^1}^2 \leq C, \quad \int_0^T \|u^{(n)}(t)\|_{H^1}^2 dt \leq C
\]
and
\[
\int_0^T \|\partial_t u^{(n)}(t)\|_{L^2}^2 dt \leq C.
\]

We now use standard methods to show that we have a solution of the limiting equation (cf. for example Temam [16]). Indeed by compactness results, there is a subsequence $(n_k)_{k \in \mathbb{N}}$, such that $u^{n_k} \to u$ weakly in $L^2([0, T], H^2)$ and $H^1([0, T], L^2)$, and strongly in $L^p([0, T], L^2)$ for any $p > 1$. Thus $u$ is the weak solution of Burgers equation, i.e. it solves the PDE in $L^2([0, T], L^2)$. As weak solutions of the Burgers equation are unique, we can neglect the subsequence, as any limiting point of $u^{(n)}$ defines the same solution $u$. Finally, the convergence is strong enough, in order to have all Fourier coefficients convergent. Thus for all $k \in \mathbb{Z}$ the Fourier coefficients $u_k$ of $u$ are given by
\[
u_k(t) = \lim_{n \to \infty} u_k^{(n)}(t) = \lim_{n \to \infty} w_k^{(n)} \chi_k(t).
\]

**Remark 5.4.** We point out that the assumptions of the previous theorem are by no means optimal. We have used a simplified method of proof, in order to provide an example in a simple context. In particular the constraint on the initial condition can be relaxed. Furthermore, using regularisation properties of the PDE, we can always get sufficiently smooth initial conditions, if we wait a small amount of time.
