Received January 10, 2008

Polychlorinated biphenyls (PCBs) can be oxygenated to form very reactive hydroquinone and quinone products. A guiding hypothesis in the PCB research community is that some of the detrimental health effects of some PCBs are a consequence of these oxygenated forms undergoing one-electron oxidation or reduction, generating semiquinone radicals (SQ\(^{−}\)). These radicals can enter into a futile redox cycle resulting in the formation of reactive oxygen species, that is, superoxide and hydrogen peroxide. Here, we examine some of the properties and chemistry of these semiquinone free radicals. Using electron paramagnetic resonance (EPR) to detect SQ\(^{−}\) formation, we observed that (i) xanthine oxidase can reduce quinone PCBs to the corresponding SQ; (ii) the heme-containing peroxidases (horseradish and lactoperoxidase) can oxidize hydroquinone PCBs to the corresponding SQ; (iii) tyrosinase acting on PCB ortho-hydroquinones leads to the formation of SQ; (iv) mixtures of PCB quinone and hydroquinone form SQ\(^{+}\) via a comproportionation reaction; (v) SQ\(^{−}\) are formed when hydroquinone-PCBs undergo autoxidation in high pH buffer (>pH 8); and, surprisingly, (vi) quinone-PCBs in high pH buffer can also form SQ\(^{−}\); (vii) these observations along with EPR suggest that hydroxide anion can add to the quinone ring; (viii) \(\text{H}_2\text{O}_2\) in basic solution reacts rapidly with PCB-quinones; and (ix) at near-neutral pH SOD can catalyze the oxidation of PCB-hydroquinone to quinone, yielding \(\text{H}_2\text{O}_2\). However, using 5,5-dimethylpyrroline-1-oxide (DMPO) as a spin-trapping agent, we did not trap superoxide, indicating that generation of superoxide from SQ\(^{−}\) is not kinetically favorable. These observations demonstrate multiple routes for the formation of SQ\(^{−}\) from PCB-quinones and hydroquinones. Our data also point to futile redox cycling as being one mechanism by which oxygenated PCBs can lead to the formation of reactive oxygen species, but this is most efficient in the presence of SOD.

Introduction

Polychlorinated biphenyls (PCBs) are a class of environmental pollutants that have from one to 10 chlorines substituted on the phenyl rings. PCBs have been widely used from the 1930s to the 1960s in diverse industrial applications, including cooling and insulating fluids for industrial transformers and capacitors, hydraulic fluids, and sealants (1, 2). PCBs are known to elicit various adverse effects, including carcinogenicity, neuroendocrine disturbances, developmental and reproductive toxicity, and immunotoxicity (3, 4). PCBs have been implicated in or related to cancer such as malignant melanoma, breast, and lung cancers in exposed populations (5). The production of PCBs was banned in the 1970s due to the high toxicity of most PCB congeners and mixtures. However, because of their physical and chemical properties, PCBs are quite stable; thus, they remain as ubiquitous environmental contaminants, which are frequently found as complex mixtures of isomers and congeners in air, water, soil, and dust on surfaces in homes and in factories (6).

Lower halogenated PCBs have been shown to be metabolized by rat microsomes to phenol and dihydroxybiphenyl metabolites (7–9). Robertson et al. have reported that the primary metabolites of 4-monochlorobiphenyl are 4′-chloro-2-hydroxybiphenyl, 4′-chloro-3-hydroxybiphenyl, and 4′-chloro-4-hydroxybiphenyl; these phenolic compounds can then subsequently undergo a second hydroxylation yielding 4′-chloro-3,4-dihydroxybiphenyl, 4′-chloro-2,3-dihydroxybiphenyl, and 4′-chloro-2,5-dihydroxybiphenyl (10). These para-dihydroxy PCBs and catechol type ortho-dihydroxy PCBs can be further oxidized to reactive quinones.

Early research suggests that the intracellular activation of hydroquinones and quinones producing relatively stable semi-quinone free radicals is an important step to account for their cytotoxicity (11). Radicals produced “downstream”, such as superoxide anion radical (\(\text{O}_2^{−}\)), will lead to hydrogen peroxide and hydroxyl radical formation (\(\text{HO}^{•}\)); these reactive oxygen species will deplete antioxidants and potentially lead to an increase in oxidative stress (12–15). These reactive oxygen species can oxidize lipids, proteins, and DNA (16–18).

In the work reported here, we used EPR to examine the many routes that can lead to the formation of PCB-semiquinone radicals. We also examined the different spectral patterns of these various semiquinone radicals and used the changes observed in the EPR spectra to understand their chemistry.

Materials and Methods

Caution: PCB derivatives should be handled as hazardous compounds in accordance with NIH guidelines.

Materials. Hypoxanthine (HX),\(^1\) xanthine oxidase (XO), horseradish peroxidase (HRP), tyrosinase (TYR), lactoperoxidase (LPO), catalase (Cat), superoxide dismutase (SOD), and diethylenetriaminepentaacetic acid (DETAPAC or DTPA) were from Sigma (St. Louis, MO); benzoquinone, hydroquinone, phenyl-quinone, sodium hydroxide, and \(\text{H}_2\text{O}_2\) were from Fisher;

and quinhydrone was from Alfa Aesar (Ward Hill, MA). DMPO was from Dojindo Laboratories (Japan). Materials were used without further purification. The various PCB hydroquinones and quinones were synthesized as previously described (19–21).

Stock solutions (200 mM each) of PCBs were prepared in DMSO. Stock solutions of HX (10 mM), HRP (0.2 U/µL), TYR (1 U/µL), H2O2 (20 mM), SOD (100 U/µL), and Cat (20 U/µL) were prepared with Nanopure water just before use; XO (10.8 mU/µL) and LPO (208 mU/µL) were used as received. All experiments were carried out in 100 mM phosphate buffer at room temperature. Typical EPR parameters were as follows: 3511 G center field; 15 or 80 G sweep width (for the spin locking experiments with DMPO); 9.854 GHz microwave frequency; 20 mW power; 2 × 105 receiver gain; modulation frequency of 100 kHz; modulation amplitude of 1 or 0.1 G; with the conversion time and time constant both being 40.96 ms with 5 X-scans for each 1024 point spectrum.

The final concentrations of PCB derivatives were 100 µM unless specifically mentioned. Alkaline solutions (pH 10) were prepared with 5 M sodium hydroxide solution. All of the PCB quinones and hydroquinones studied are shown in Figure 1.

**EPR Spectroscopy.** EPR spectroscopy was done using a Bruker EMX spectrometer equipped with a high-sensitivity cavity and an Aqua-X sample holder. Spectra were obtained at room temperature. Typical EPR parameters were as follows: 3511 G center field; 15 or 80 G sweep width (for the spin trapping experiments with DMPO); 9.854 GHz microwave frequency; 20 mW power; 2 × 105 receiver gain; modulation frequency of 100 kHz; modulation amplitude of 1 or 0.1 G; with the conversion time and time constant both being 40.96 ms with 5 X-scans for each 1024 point spectrum.

The final concentrations of PCB derivatives were 100 µM unless specifically mentioned. Alkaline solutions (pH 10) were prepared with 5 M sodium hydroxide solution. All experiments were carried out in 100 mM phosphate buffer at room temperature; 3.00 mL of PBS buffer was loaded in the cuvette, stirring with a small stirring bar to ensure that the solution mixed well. Using the kinetics setting, the change in absorbance at 249 nm was recorded vs time.

**Oxygen Uptake.** Oxygen uptake was determined with a Clark type electrode using an YSI model 5300 Biological Oxygen Monitor (Yellow Springs Instrument Co., Yellow Springs, OH). All measurements were made at room temperature; 1.00 mL of PBS buffer was loaded in the cuvette, and aerated by stirring for 5 min, and then, the electrode was placed in contact with the solution, leaving no headspace for air and ensuring that all air bubbles were removed. After a 2 min equilibration, reagents were introduced through the access slot, and then, oxygen consumption was monitored. Each experiment was repeated at least three times. Results of replicate experiments varied less than ±10%.

**UV–Vis Spectroscopy.** UV spectra were recorded with a Hewlett-Packard 8453 diode array spectrometer. All measurements were made at room temperature; 1.00 mL of PBS buffer was loaded in the cuvette, stirring with a small stirring bar to ensure that the solution mixed well. Using the kinetics setting, after the introduction of reagents, the change in absorbance at 249 nm was recorded vs time.

**Results and Discussion.**

The generation of semiquinone radicals by oxidation/reduction of hydroquinones and quinones is well-documented (22–25). Polychlorinated biphenyls can be oxidized to hydroquinones (H2Q) and quinones (Q). These species can be converted to their corresponding semiquinone free radical (1:4:6:4:1 intensity ratio, aH (4)) (26).

**Scheme 1. Reaction Pathways of PCB Hydroquinone, Semiquinone, And Quinone**

![Scheme 1](image)

*High pH implies values greater than 8 or 9, as seen in Figure 7. Tyrosinase only acts on ortho-hydroquinones.*

1 Abbreviations: aH (4), hyperfine splitting constant due to four identical hydrogens; aH (3), hyperfine splitting due to the hydrogen on position 3 of the PCB phenyl ring; BQ, benzoquinone; Cat, catalase; DETAPAC, diethylenetriaminepentaacetic acid; DMPO, 5,5-dimethylpyrroline-1-oxide; H2Q, hydroquinone; HRP, horseradish peroxidase; HX, hypoxanthine; LPO, lactoperoxidase; MnSOD, manganese-containing superoxide dismutase; PQ, phenyl-quinone; Q, quinone; QH, quinhydrone; SOD, superoxide dismutase; SQ−, semiquinone; TYR, tyrosinase; xH, represents a generic number of chlorines, each at a position n on the secondary ring; XO, xanthine oxidase.
lactoperoxidase (LPO) are the enzymes known to catalyze H2O2-

HX/XO, [HX] increases the rate of autoxidation of hydroquinone and
decomposition of hydroquinone and quinone. In air-saturated buffer at pH 7.4, 100 µM ortho-
hydroquinone 4'-Cl-3,4-H2Q produced a small background EPR signal of 4'-Cl-3,4-SQ− (at the noise level), due to the slow oxidation of the hydroquinone (not shown). However, in the presence of TYR, a much stronger EPR spectrum of SQ− from 4'-Cl-3,4-H2Q was observed (Figure 2e). When a para-hydro-
quinone was exposed to TYR, no increase in SQ− was observed (not shown). In the EPR experiments, if too much TYR was introduced into the incubation such that all of the hydroquinone was very rapidly oxidized to quinone, the EPR signal of SQ− was quite weak or below the limit of detection.

If reaction mixtures identical to those used for EPR were monitored for oxygen consumption, the predicted stoichiometric loss of oxygen was observed with ortho-hydroquinones, while no oxygen was lost with para-hydroquinones. These results demonstrate that ortho-hydroquinone-PCBs have additional mechanisms for radical formation as compared to para-hydroquinone PCBs.

**Autoxidation in Aerobic Solutions.** When the phenolic OH groups of hydroquinones ionize, the anions are prone to rapid autoxidation. Indeed, the semiquinone radical of hydroquinone was observed by EPR spectroscopy in the 1950s when it was introduced to oxygenated, alkaline media (31). We hypothesized that hydroquinone derivatives of PCBs would also undergo a parallel autoxidation reaction and generate corresponding PCB semiquinones (Scheme 2A). To examine this hypothesis, we introduced 2'-Cl-2,5-H2Q to an alkaline environment (pH 10); we obtained the corresponding SQ− radical (Figure 2f and Table 1). It has been suggested that the generation of SQ− in alkaline solution is only the first stage of the autoxidation of dihydroxy phenols (32–34). The radical can continue to oxidize to quinone, and then, a comproportionation reaction will turn one molecule of hydroquinone and one molecule of quinone into two molecules of SQ− (Scheme 2B). Increasing the pH from 7 to 12 dramatically increased the concentration of the initially formed SQ−; this is because high [OH−] increases the rate of autoxidation of hydroquinone and decreases the rate of decay of SQ−, principally by disproportionation (Scheme 1), which is dependent on [H+]2 (35).

Using the HX/XO system, we have shown above that PCB quinones can be reduced by one electron to corresponding PCB semiquinone radicals. In addition, H2O can be oxidized to form SQ−; high pH can increase this rate. However, a most surprising observation is that 2'-Cl-2,5-Q in high pH solution also generates a strong SQ− signal (Figure 2g). To generate SQ− from Q, there must be a source of electrons. In this experiment, we observed that the EPR signal for the initial SQ− (~1:3:3:1) radical gives way to a 1:2:1 spectrum, consistent with the formation of a secondary radical SQ(II)−. A possible mechanism for the continued autoxidation PCB quinone is described in Scheme 2C. The evolution of the EPR spectrum from a ~1:3:3:1 pattern to a 1:2:1 pattern indicates the loss of a hydrogen from the quinone ring (Figure 3). This suggests a base-catalyzed Michael addition of an

**Figure 2.** Semiquinone radical (SQ−) can be formed by many routes: (a) SQ− generated from BQ reacted with HX/XO, [HX] = 50 µM, [XO] = 20 mU/mL; (b) SQ− generated from 2'-Cl-2,5-Q reacted with HX/XO, [HX] = 50 µM, [XO] = 20 mU/mL; (c) SQ− generated from 2'-Cl-2,5-H2O reacted with HX/XO, [HX] = 50 µM, [XO] = 20 mU/mL; (d) SQ− generated from 2'-Cl-2,5-H2O reacted with HX/XO, [HX] = 50 µM, [XO] = 20 mU/mL; (e) SQ− generated from 2'-Cl-2,5-H2O reacted with HX/XO, [HX] = 50 µM, [XO] = 20 mU/mL; (f) SQ− generated from 2'-Cl-2,5-Q reacted with TYR, [TYR] = 2.5 U/mL; (g) SQ− generated from 2'-Cl-2,5-Q reacted with TYR, [TYR] = 2.5 U/mL; (h) SQ− generated from 2'-Cl-2,5-Q reacted with TYR, [TYR] = 2.5 U/mL. The EPR modulation amplitude was 1 G for spectra a−e and h and 0.1 G for spectra f and g.

PCB quinones can be viewed as substituted benzoquinone (Figure 1). Addition of the PCB-quinone 2'-Cl-2,5-Q to the HX/XO system (pH 7.4) resulted in a distinct four-line spectrum (Figure 1). This introduction of quinone will allow the formation of SQ− via the comproportionation of hydroquinone and quinone. In air-saturated buffer at pH 7.4, 100 µM ortho-hydroquinone 4'-Cl-3,4-H2Q produced a small background EPR signal of 4'-Cl-3,4-SQ− (at the noise level), due to the slow oxidation of the hydroquinone (not shown). However, in the presence of TYR, a much stronger EPR spectrum of SQ− from 4'-Cl-3,4-H2Q was observed (Figure 2e). When a para-hydroquinone was exposed to TYR, no increase in SQ− was observed (not shown). In the EPR experiments, if too much TYR was introduced into the incubation such that all of the hydroquinone was very rapidly oxidized to quinone, the EPR signal of SQ− was quite weak or below the limit of detection.

If reaction mixtures identical to those used for EPR were monitored for oxygen consumption, the predicted stoichiometric loss of oxygen was observed with ortho-hydroquinones, while no oxygen was lost with para-hydroquinones. These results demonstrate that ortho-hydroquinone-PCBs have additional mechanisms for radical formation as compared to para-hydroquinone PCBs.

**Autoxidation in Aerobic Solutions.** When the phenolic OH groups of hydroquinones ionize, the anions are prone to rapid autoxidation. Indeed, the semiquinone radical of hydroquinone was observed by EPR spectroscopy in the 1950s when it was introduced to oxygenated, alkaline media (31). We hypothesized that hydroquinone derivatives of PCBs would also undergo a parallel autoxidation reaction and generate corresponding PCB semiquinones (Scheme 2A). To examine this hypothesis, we introduced 2'-Cl-2,5-H2Q to an alkaline environment (pH 10); we obtained the corresponding SQ− radical (Figure 2f and Table 1). It has been suggested that the generation of SQ− in alkaline solution is only the first stage of the autoxidation of dihydroxy phenols (32–34). The radical can continue to oxidize to quinone, and then, a comproportionation reaction will turn one molecule of hydroquinone and one molecule of quinone into two molecules of SQ− (Scheme 2B). Increasing the pH from 7 to 12 dramatically increased the concentration of the initially formed SQ−; this is because high [OH−] increases the rate of autoxidation of hydroquinone and decreases the rate of decay of SQ−, principally by disproportionation (Scheme 1), which is dependent on [H+]2 (35).

Using the HX/XO system, we have shown above that PCB quinones can be reduced by one electron to corresponding PCB semiquinone radicals. In addition, H2O can be oxidized to form SQ−; high pH can increase this rate. However, a most surprising observation is that 2'-Cl-2,5-Q in high pH solution also generates a strong SQ− signal (Figure 2g). To generate SQ− from Q, there must be a source of electrons. In this experiment, we observed that the EPR signal for the initial SQ− (~1:3:3:1) radical gives way to a 1:2:1 spectrum, consistent with the formation of a secondary radical SQ(II)−. A possible mechanism for the continued autoxidation PCB quinone is described in Scheme 2C. The evolution of the EPR spectrum from a ~1:3:3:1 pattern to a 1:2:1 pattern indicates the loss of a hydrogen from the quinone ring (Figure 3). This suggests a base-catalyzed Michael addition of an

$^a$ These hyperfine splittings (in Gauss) are the results from simulations of the experimental spectra. Assignment of hyperfine splittings to particular hydrogens on the semiquinone ring followed examples of previously published work (36–38). On the secondary ring, we make no definite assignments. The numbering pattern is for the structure:

\[
\begin{array}{cccccc}
3'&2'&1&2&3&4 \\
5'&6'& & & & \\
\end{array}
\]

$^b$ In Gauss.

OH$^-$ to the quinone ring (OH$^-$ can in principle substitute for any of the three hydrogens on the quinone ring; only one possibility is shown) (Scheme 2C). When quinone is introduced to an alkaline solution, we initially see only the primary...
radical, SQ$^{-}$; the secondary radical SQ(II)$^{--}$ is observed after some time has passed, indicating that the reaction is somewhat slow and a significant amount of the trihydroxy compound must be formed before the 1:2:1 spectrum can be observed. The addition of OH$^-$ to the quinone ring provides the reducing equivalents to form the initial SQ$^{-}$ observed as well as SQ(II)$^{--}$ (Scheme 2C).

**SQ$^{-}$ Via Comproportionation.** To demonstrate that SQ$^{-}$ can be formed by the comproportionation reaction of H$_2$Q and Q, we examined by EPR solutions containing both species (Scheme 2B). We used quinhydron, a charge transfer complex consisting of equal parts of hydroquinone interacting with benzoquinone through ring stacking, as a test system; a strong EPR spectrum for the benzosemiquinone radical was observed in neutral solution consistent with an equilibrium comproportionation reaction (spectrum not shown; it has the same characteristics as the spectrum of Figure 2a). When 2'-Cl-2,5-Q and 2'-Cl-2,5-H$_2$Q were mixed (1:1 ratio, 50 µM each) in neutral solution, the corresponding SQ$^{-}$ radical was observed by EPR (Figure 2h). When the ratio of H$_2$Q:Q was varied over the range of 1:9 to 9:1 (keeping [H$_2$Q] + [Q] = 100 µM), SQ$^{-}$ was observed at all ratios with approximately the same intensity. This is consistent with comproportionation and disproportionation reactions achieving equilibrium rapidly, on the time scale of the EPR observations, with an accompanying autoxidation reaction removing the radical. As expected, the intensity of the EPR signal increased with increasing pH. At high pH, the hydroquinone will ionize, leading to a more rapid autoxidation; in addition, the disproportionation reaction is slowed, as protons are needed, thus a higher EPR signal intensity.

**Characterization of SQ$^{-}$ Generated from a Wide Range of Oxygenated PCBs.** Because semiquinone radicals are more stable in alkaline solution, we generated a series of PCB semiquinone radicals at pH 10 to investigate the influence of the chemical structure on the EPR spectra (Figure 4). Here, we focus on the initially formed, primary radicals that are observed upon raising the pH to 10.

The EPR spectra of the SQ$^{-}$ generated from different x$_n$'-Cl-2,5-H$_2$Q and x$_n$'-Cl-2,5-H$_2$Q are quite similar (Figure 4A,B); starting with either the quinone or the hydroquinone of a specific x$_n$'-Cl-2,5-H$_2$Q, the same semiquinone spectrum was observed. Hyperfine splitting constants, derived from simulation (Table 1), showed three nearly identical hydrogens, which yield a 1:3:3:1 four-line spectrum. These results show that the primary interactions are with the hydrogens on the semiquinone ring; the other ring provides no unique splittings, perhaps only contributing to the line width.

There are two different families of PCB ortho-hydroquinones, 2,3-H$_2$Q and 3,4-H$_2$Q. When oxidized to their corresponding SQ$^{-}$, each member of a family produced a similar EPR spectral pattern (Figure 4C,D and Table 1). Successful simulations of spectra from 2,5-SQ$^{-}$ or 2,3-SQ$^{-}$ did not require any contributions of hyperfine splittings from the other phenyl ring. However, for the 3,4-SQ$^{-}$ (Figure 4D), hyperfine splittings from the second phenyl ring contributed markedly. Definitive assignments of hyperfine splittings to specific H or Cl atoms from the second phenyl ring (the phenyl ring with Cl) have not been made (Table 1). We have used the literature (36–38) to guide our assignment of the hyperfine splitting constants for the hydrogens on the semiquinone ring. The simulation results are consistent with low spin density on the secondary ring. However, the x$_n$'-Cl-3,4-SQ$^{-}$ radicals show considerable spin density on the secondary ring, especially 4'-Cl-3,4-SQ$^{-}$.

**Spin Trapping with DMPO.** Semiquinones can transfer an electron to oxygen generating the superoxide radical (18, 39). Superoxide can play a key role in the generation of oxidative damage under various pathophysiological conditions. However, O$_2^-$ is very short-lived, and in most cases, the sensitivity of EPR spectroscopy is insufficient for direct detection. Thus, we used EPR spin trapping to probe for the formation of superoxide radicals (40–42). A spin trap reacts with short-lived radicals to form much longer-lived spin adducts that accumulate to a level detectable by EPR.

In Figure 5, spectrum “a” is a control demonstrating the absence of artificial signals from DMPO. Spectrum “b” represents the typical DMPO/OOH spin adduct generated from HX/XO system and trapped by DMPO; some DMPO/HO$^+$ spin adduct is also present. When 2'-Cl-2,5-Q was added to DMPO in neutral solution, both SQ$^{-}$ and DMPO/HO$^+$ were detected (Figure 5c). If SOD was included, there was no significant change in the intensity of the spectrum of SQ$^{-}$ (spectrum “d”), but the signal of the DMPO/HO$^+$ radical increased. Because no evidence for DMPO/OOH radical was observed in “c” and SOD did not decrease the DMPO/HO$^+$ signal, there appears to be no significant superoxide formation from 2'-Cl-2,5-Q.

When 2'-Cl-2,5-H$_2$Q was substituted for 2'-Cl-2,5-Q, the addition of SOD stimulated the generation of SQ$^{-}$ (Figure 5e,f); the intensity of the SQ$^{-}$ spectrum increased over time, reached a steady state, and then decreased (data not shown). Cat had no effect on the generation of SQ$^{-}$ or DMPO/HO$^+$ radical (not shown). These observations indicate that generation of superoxide from SQ$^{-}$, reaction 1, is not kinetically or thermodynamically favorable.

\[
SQ^{-} + O_2 \rightarrow O_2^{2--} + Q \tag{1}
\]

The equilibrium for this reaction lies far to the left. Using benzoquinone and various substituted quinones as references, the rate constant for the forward reaction will be approximately $10^{9}$–$10^{5}$ M$^{-1}$ s$^{-1}$, while the rate constant for the reverse reaction is on the order of $10^9$ M$^{-1}$ s$^{-1}$ (18, 43, 44). This rapid back reaction explains why our spin trapping experiment cannot detect superoxide formation.

**SOD Catalyzes the Autoxidation of Hydroquinone as Seen by UV Spectroscopy.** The increase in [SQ$^{-}$] observed in Figure 5f suggests that SOD can catalyze the autoxidation of 2'-Cl-2,5-H$_2$Q to 2'-Cl-2,5-Q. To observe if the rate of formation of 2'-Cl-2,5-Q increases when SOD is added to a near-neutral solution of 2'-Cl-2,5-H$_2$Q, we used UV spectroscopy to follow the rate of formation of 2'-Cl-2,5-Q. In the absence of SOD, the autoxidation of 2'-Cl-2,5-H$_2$Q (100
µM to quinone is relatively slow (Figure 6a,b). When SOD is present at time zero, there is no change in the initial rate of autoxidation; however, after about 10 min or so, autoxidation accelerates (Figure 6c). If a trace of 2′′-Cl-2,5-Q (1 µM) is introduced at time zero along with SOD, there is no lag time for a much more rapid rate of autoxidation. These observations are parallel to those observed by Eyer in a study of hydroquinone autoxidation (44); this same process appears to hold with coenzyme Q semiquinone radical in mitochondria with changes in MnSOD (45). Superoxide is formed by reaction 1; however, the equilibrium lies far to the left. SOD pulls this equilibrium before it enters the back reaction due to its very rapid dismutation of superoxide, reaction 2.

Figure 4. Semiquinone radical generated from PCB with different substitution patterns at pH 10 and computer simulations. Hyperfine splittings and spectral line widths derived by simulation of experimental spectra are presented in Table 1. (A) Semiquinone radicals generated from different 2,5-Q at pH 10: (a) SQ− generated from 4′-Cl-2,5-Q; (b) SQ− generated from 3′-Cl-2,5-Q; (c) SQ− generated from 3′,4′-Cl-2,5-Q; and (d) SQ− generated from PQ. (B) Semiquinone radicals generated from different 2,5-H2Q at pH 10: (a) SQ− generated from 4′-Cl-2,5-H2Q; (b) simulation of 4′-Cl-2,5-SQ−; and (c) SQ− generated from 3′-Cl-2,5-H2Q. (C) Semiquinone radicals generated from different 2,3-H2Q at pH 10: (a) SQ− generated from 4′-Cl-2,3-H2Q; (b) simulation of 4′-Cl-2,3-SQ−; and (c) simulation of 3′,4′-Cl-2,3-SQ−. (D) Semiquinone radicals generated from different 3,4-H2Q at pH 10: (a) SQ− generated from 4′-Cl-3,4-H2Q; (b) simulation of 4′-Cl-3,4-SQ−; (c) SQ− generated from 2′,5′-Cl-3,4-H2Q; (d) simulation of 2′,5′-Cl-3,4-SQ−; (e) SQ− generated from 2′,3′-Cl-3,4-H2Q; and (f) simulation of 2′,3′-Cl-3,4-SQ−. All experimental spectra were collected using a 0.1 G modulation amplitude.
2H^+ + 2O_2 \xrightarrow{\text{sod}} O_2 + H_2O_2 \quad (2)

In the experiment of Figure 6c, the rate of autoxidation remains low until significant 2'-Cl-2,5-Q is generated, allowing for the comproportionation reaction of 2'-Cl-2,5-Q with 2'-Cl-2,5-H_2Q to form SQ'^-, reaction 3. However, if a trace of 2'-Cl-2,5-Q is introduced at time zero (Figure 6d), no lag time is observed because all of the ingredients are present to make significant SQ'^-.

H_2Q + O_2 \rightleftharpoons 2SQ'^- + 2H^+ \quad (3)

These observations suggest that oxygen will be consumed in the autoxidation reaction, giving rise to the formation of H_2O_2, the net reaction being

H_2Q + O_2 \rightarrow H_2O_2 + Q \quad (4)

**Oxygen Consumption. Oxygen Uptake at Near-Neutral pH.** If SOD accelerates the rate of oxidation of 2'-Cl-2,5-H_2Q as seen by formation of quinone, then the rate of oxygen consumption should also increase. Indeed, when 2'-Cl-2,5-H_2Q (500 \mu M) was introduced into pH 7.4 PBS, the rate of oxygen consumption paralleled all of the results of Figure 6 (data not shown). The introduction of Cat to a partially oxidized solution of 2'-Cl-2,5-H_2Q demonstrated that nearly all of the oxygen consumed was present as H_2O_2. These observations support reactions 1–4 as being operative in this system.

**Oxygen Uptake in Alkaline pH Solutions.** Autoxidation of 2'-Cl-2,5-H_2Q in alkaline pH is accelerated due to ionization of the phenolic hydroxyls and subsequent one-electron oxidation to 2'-Cl-2,5-SQ'^-, followed by loss of a second electron yielding 2'-Cl-2,5-Q. One might predict that 1 equiv of H_2Q would consume 1 equiv of dioxygen, yielding 1 equiv of H_2O_2 (reaction 4). Interestingly, the amount of oxygen consumed is a function of pH (Figure 7). We observed a sharp increase in the amount of oxygen consumed as the pH was increased from pH 8 to pH 13. At higher pH values, we observed that H_2Q consumed almost 2 equiv of oxygen, rather than the 1 equiv anticipated; unexpectedly, we observed that the quinone also consumed oxygen in a pH-dependent manner. The amounts of oxygen consumed by H_2Q and Q paralleled each other; the quinone form always consumed one-half equiv less oxygen than H_2Q at a particular pH. These observations are consistent with oxidation of hydroquinone to quinone, followed by the nucleophilic addition of OH^- to the quinone forming a trihydroxy compound that can be oxidized in the high pH environment (Scheme 2C). When starting with the quinone, there would be no initial oxidation; thus, less oxygen would be consumed.

The rate of consumption of oxygen is dramatically increased upon initiating a pH jump of a near-neutral solution of the oxygenated PCBs that we examined (Figure 7). If reaction 4 is operative, then H_2O_2 should be formed. We investigated this possible formation of H_2O_2 using 2'-Cl-2,5-H_2Q and 2'-Cl-2,5-
Q. Cat disproportionates 2H₂O₂ into 2H₂O and 1O₂; thus, it
can be used as a tool to examine the stoichiometry of the
reduction O₂ to H₂O₂. In near-neutral solution, little or no
oxygen was consumed after introduction of 2'-Cl-2,5-H₂Q
(Table 2, exp 1). However, if the pH is increased to ≈12 by
the addition of NaOH, a rapid loss of oxygen occurs (−170
µM) (Table 2, exp 2). If reaction 4 holds, we would have
expected to lose only 100 µM O₂. These observations are
consistent with Figure 7 and the reactions outlined in Scheme
2C. Most surprising was our observation that upon introduction
of Cat, little if any oxygen returned, indicating that there was
no hydrogen peroxide in the system. (Although high pH
inactivates enzymes, this high pH did not inactivate Cat in the
short time frame of an experiment; data not shown.)

To determine if the hydroquinone reacts directly with H₂O₂,
we introduced 100 µM H₂O₂ into a neutral solution of 100 µM
2'-Cl-2,5-H₂Q. After 15 min, all of the H₂O₂ was still present
as the introduction of Cat saw the return of 50 µM O₂ (Table
2, exp 3). Thus, there is no rapid direct reaction of hydroquinone
with H₂O₂. In exp 4, we introduced H₂O₂ after the reactions
initiated by the pH jump were complete. The addition of Cat
resulted in the return of 50 µM O₂, demonstrating that there
was no rapid direct reaction of H₂O₂ with the oxidation products
of 2'-Cl-2,5-H₂Q. Interestingly, the introduction of H₂O₂ before
the pH jump reduced oxygen consumption (−170 to −90 µM;
Table 2, exp 5). Cat returned only 30 µM oxygen, indicating
that some of the H₂O₂ was lost. Experiments 1–5 of Table 2
indicate that H₂O₂ must be reacting with intermediates in the
oxidation reactions of 2'-Cl-2,5-H₂Q.

Hydrogen peroxide has been shown to react with benzoquinone
(46) and chlorinated benzoquinone (47). Experiments 6–10 of
Table 2 examine the possible reaction of H₂O₂ with a typical PCB-
quinone, 2'-Cl-2,5-Q. At near-neutral pH, there was no apparent
reaction of H₂O₂ with 2'-Cl-2,5-Q (exp 8). However, experiments
7 and 10 show a considerable loss of H₂O₂ upon a pH jump. An
explanation for this observation is that in pH 12 solution, some
H₂O₂ will be deprotonated (pKₐ for H₂O₂ to form OOH⁻ is 11.7,
48). The peroxide anion is a powerful nucleophile, much more
reactive than hydroxide anion (47). It will react with PCB quinone,
similar to OH⁻; however, the reaction will likely be much faster
(Scheme 2D). Thus, experiments 7 and 10 in Table 2 with 2'-Cl-
2,5-Q are consistent with a rapid nucleophilic addition reaction of
H₂O₂, via OOH⁻, to the quinone.

### Table 2. Oxygen Uptake and Changes in [H₂O₂] upon Oxidation of 2'-Cl-2,5-H₂Q or 2'-Cl-2,5-Q by Increasing the pH

| additions                          | change in oxygen concentration (µM) | change in oxygen concentration (µM) |
|------------------------------------|------------------------------------|------------------------------------|
|                                    | exp 1     | exp 2     | exp 3     | exp 4     | exp 5     |
| 2'-Cl-2,5-H₂Q (100 µM)              | 0         | 0         | 0         | 0         | 0         |

| H₂O₂ (100 µM)                      |           |           |           |           |           |
| Cat (150 U/mL)                     | 0         | +<5       | +50       | +50       | +50       |
| expected with Cat                   | 0         | +35       | +50       | +50       | +50       |

*a Each experiment was done at least three times. Variations between experiments are on the order of 10%. *b Each entry represents the change in oxygen concentration after the addition. The additions were made sequentially as shown down column 1. *c In PBS, pH 7.4. *d The actual loss of oxygen is less than or on the order of the drift of the instrument, which typically is less than 5 µM per 15 min. *e A blank cell indicates that there was no addition of this reagent and thus no change in [O₂]. *f The addition of 20 µL of 5 M NaOH into 2 mL of buffer increases the pH of solution to over 12. *g Expected return of oxygen assuming that the only important reaction upon introduction of NaOH is reaction 2 when hydroquinone is reactant; if quinone is the reactant, the expected return of oxygen assumes no reaction between the quinone and the H₂O₂.

### Conclusions

In this work, we have demonstrated the following:
1. The same semiquinone radical is produced when a PCB-
hydroquinone undergoes a one-electron oxidation or the
quinone form undergoes a one-electron reduction. This can
be accomplished many different ways, including the following:
(a) Xanthine oxidase can reduce quinone PCBs to the
corresponding SQ⁻.
(b) The heme-containing peroxidases (horseradish and lact-
toperoxidase) can oxidize hydroquinone PCBs to the
corresponding SQ⁻.
(c) Tyrosinase acting on PCB ortho-hydroquinones leads to
formation of SQ⁻.
(d) SQ⁻ is formed rapidly when hydroquinone-PCBs under-
ago air oxidation in high pH buffer (≈pH 8).
(e) Quinone-PCBs in high pH buffer can also form SQ⁻.
(f) Mixtures of PCB-quinone and hydroquinone form SQ⁻ via
a comproportionation reaction.

2. The EPR spectra of semiquinone radicals produced from
structurally similar PCB hydroquinones and quinones had
similar spectral patterns as characterized by hyperfine splittings.
3. The production of superoxide radicals could not be observed
using DMPO as a spin trapping agent due to the rapid reaction
of superoxide with quinone; however, SOD accelerates the
autoxidation of hydroquinone indicating a role for superoxide.
4. At higher pH, hydroxide anion can add to the quinone ring
of a PCB-quinone, leading to the formation of a new
hydroquinone and rupture of the quinone ring.
5. Using oxygen consumption at higher pH, the autoxidation
of both hydroquinone and quinone consumed oxygen—this
oxygen consumption could be greater than the 1:1 stoichi-
ometry predicted by reaction 2.
6. H₂O₂ does not accumulate when a PCB-hydroquinone
autoxidizes at high pH; H₂O₂ appears to react with inter-
mediates formed during the oxidation process.
7. H₂O₂ accumulates when SOD is present in an autoxidizing
PCB-hydroquinone solution at near-neutral pH; without
SOD, the reaction is too slow to observe any loss of O₂ or accumulation of H₂O₂.
