Small-Scale Fluctuations in Cosmic X-ray Background:  
A Power Spectrum Approach

Equations to investigate fluctuations in cosmic X-ray background radiation due to point-like sources at high-redshift are formulated in a systematic way. The angular power spectrum of X-ray background fluctuations is investigated from large-scales to small-scales in various cosmological models such as open universe models and models with the cosmological constant, assuming a simple evolution model of the sources. The effect of epoch-dependent bias is demonstrated for small-angle fluctuations. The contribution from shot noise fluctuations is also discussed.

I. INTRODUCTION

Cosmic X-ray background (CXB) has been studied for long time in astrophysics [1]. Recently several authors have discussed the possibility of the CXB fluctuations as a probe of the structure formation in the high redshift universe [2,3]. These works are motivated from observational results of the deep survey carried out by ROSAT, which resolved a significant fraction of the X-ray background into sources (∼70%). It turns out to be that most of the sources are extra-galactic objects, i.e., AGN and other X-ray luminous galaxies in the high redshift universe. While situation is not so clear in the harder band, something similar would be happening. Several X-ray mission projects are in progress [4], which will give us a fine solution of the source problem in near future.

On the other hand, a scenario of the cosmic structure formation is now constrained from the observations, e.g., temperature anisotropies in the cosmic microwave background radiation (CMB) and large-scale distribution of galaxies. Future satellite experiments of CMB and survey projects of the large-scale distribution of galaxies will provide severer constraints on theoretical models of the large scale structure formation. At present the scenario introducing Cold Dark Matter (CDM) seems to be successful though some modification may be required [10,11].

Formation processes of subgalactic objects, galaxies, AGNs and clusters at the high redshift universe are one of the hottest topics in the area of astrophysics and cosmology. Since these objects are parts of the large scale structure of the universe, we could expect that information about the structure formation in the high redshift universe would be obtained by investigating them.

Several works have been done to answer following questions: Which kind of information about cosmic structure formation can be obtained from an analysis of the X-ray background fluctuations? Are they really a probe of cosmology? For example, Bougln, et al. claimed that the cross correlation between the X-ray background fluctuations and the microwave background anisotropies can provide a constraint on a cosmological constant. Small-scale fluctuations in the X-ray background have been investigated in [5,6,12–14]. On the other hand, Lahav et al. [2] calculated the angular power spectrum of the fluctuations
by a multipole expansion method. They mainly focused on large scale fluctuations and their formula is only limited to the case of the flat universe. Recently Treyer, et al. have compared the theoretical models by Lahav et al. with the observational data of HEAO1 [3].

In this paper we expand Lahav et al.’s formula to more general cosmological models, i.e., open universe models and models with the cosmological constant, and investigate general behaviors of the angular power spectrum of fluctuations from large-scales to small-scales. The X-ray background fluctuation in the open universe has been considered in ref. [15], and the similar expression was obtained. However, in that paper, the discussion was only focused on the large-scale fluctuations due to the source clustering, and the derivation of equations was very complicated. In this paper we formulate the treatment in a simple way. And the shot noise fluctuation is treated in a systematic way. The formulation developed in this paper will be useful for studying the clustering of high redshift sources not only for X-ray sources but also for other point-like sources such as radio galaxies [16,17] and γ-ray bursts.

This paper is organized as follows. In section 2 we derive expression for the angular two-point correlation function by using the multipole expansion method in a systematic way. In section 3 the fluctuations in the X-ray background are investigated assuming a simple luminosity function of X-ray sources. The competition of the fluctuations due to the source clustering and the shot noise is also studied there. Section 4 is devoted to summary and discussions. Throughout this paper we use the unit $c = 1$.

II. FORMULATION

In this section we formulate equations to calculate background fluctuations which come from point-like sources at high redshift. Essence of the formulation is divided into two parts. One is how the sources are distributed in the universe. This is the problem of source evolution and statistics of the distribution, which we describe in the latter part of this section. The other part is how the sources are observed in the sky. Which is obtained by solving light propagation in the expanding universe, if the distribution of the sources in the universe was given.

First we consider the light propagation. The photon intensity $I_\nu$ in an expanding universe is described by the radiative transfer equation:

$$\frac{\partial I_\nu}{\partial \eta} + \gamma^i \frac{\partial I_\nu}{\partial x^i} + \mathcal{H} \left[ 3I_\nu - \nu \frac{\partial I_\nu}{\partial \nu} \right] + \frac{d\gamma^i}{d\eta} \frac{\partial I_\nu}{\partial \gamma^i} = a j_\nu(x, \eta),$$

(2.1)

where $a$ is the scale factor which is normalized to be unity at present, $\eta$ is conformal time defined by $a d\eta = dt$ with the cosmic time $t$, $\mathcal{H}$ is the Hubble parameter defined as $\dot{a}/a$ with over-dot denoting $\eta$ differentiation, $\gamma^i$ is the directional vector of the photon momentum, and $j_\nu(x)$ is a field of emissivity per unit comoving volume. Assuming that an $(i)$-th point-like source is located at the coordinate $x^{(i)}$ and has the power put out per unit frequency and per unit time $L_\nu^{(i)}(\eta)$, we write the field of emissivity as

$$j_\nu(x, \eta) = \frac{1}{4\pi a^3} \sum_i L_\nu^{(i)}(\eta) \delta^{(3)}(x - x^{(i)}).$$

(2.2)

We solve equation (2.1) with (2.2) in the Friedmann-Robertson-Walker space-time with the line element

$$ds^2 = -dt^2 + a^2 \gamma_{ij} dx^i dx^j,$$

(2.3)

where $\gamma_{ij}$ is the three-metric on a space of constant negative curvature $K$:

$$\gamma_{ij} dx^i dx^j = \frac{1}{K} \left( d\chi^2 + \sinh^2 \chi (d\theta^2 + \sin^2 \theta d\phi^2) \right).$$

(2.4)

In order to take the limit of the flat universe, let us first introduce a radial coordinate $r$ instead of $\chi$ by $\chi = \sqrt{-Kr}$ and take the limit $K \to 0$. The scale factor $a$ is governed by the Friedmann equation,
\[ H^2 = \left( \frac{\dot{a}}{a} \right)^2 = H_0^2 \left( \frac{1}{a} \Omega_0 + \Omega_K + a^2 \Omega_\Lambda \right), \]  

(2.5)

where \( H_0 \) is the Hubble parameter with \( H_0 = 100 \, h \, \text{km/s/Mpc} \), \( \Omega_0 \) is the density parameter, \( \Omega_\Lambda \equiv \Lambda / 3H_0^2 \) which is the density parameter of the cosmological constant \( \Lambda \), and \( \Omega_K \equiv 1 - \Omega_0 - \Omega_\Lambda \) which describes the spatial curvature of the universe.

Employing a new variable \( f = I_{\nu}/\nu^3 \), we can rewrite equation (2.1) as

\[ \frac{\partial f}{\partial \eta} + \gamma^j \frac{\partial f}{\partial x^j} - H_\nu \frac{\partial f}{\partial \nu} + \frac{d\gamma^j}{d\eta} \frac{\partial f}{\partial \gamma^j} = \frac{a}{4\pi(\nu^3)} \sum_i L_{\nu}^{(i)}(\eta)\delta^{(3)}(x - x^{(i)}). \]  

(2.6)

Introducing \( \nu_0(= \nu a) \) instead of \( \nu \), (2.6) reduces to

\[ \frac{\partial f}{\partial \eta} + \gamma^j \frac{\partial f}{\partial x^j} + \frac{d\gamma^j}{d\eta} \frac{\partial f}{\partial \gamma^j} = \frac{a}{4\pi\nu_0^3} \sum_i L_{\nu \rightarrow \nu_0/a}^{(i)}(\eta)\delta^{(3)}(x - x^{(i)}). \]  

(2.7)

Operating \( \int_{\nu_1}^{\nu_2} d\nu_0 \nu_0^3 \) on the both side of equation (2.7), we have

\[ \frac{\partial I}{\partial \eta} + \gamma^j \frac{\partial I}{\partial x^j} + \frac{d\gamma^j}{d\eta} \frac{\partial I}{\partial \gamma^j} = \frac{a}{4\pi} \sum_i \delta^{(3)}(x - x^{(i)}) \int_{\nu_1}^{\nu_2} d\nu_0 L_{\nu \rightarrow \nu_0/a}^{(i)}(\eta), \]  

(2.8)

where \( I = \int_{\nu_1}^{\nu_2} d\nu_0 \nu_0^3 f \). Since equation (2.8) is rewritten as

\[ \frac{dI(\eta, x, \gamma)}{d\eta} = \frac{\partial I}{\partial \eta} + \gamma^j \frac{\partial I}{\partial x^j} + \frac{d\gamma^j}{d\eta} \frac{\partial I}{\partial \gamma^j} = \frac{a}{4\pi} \sum_i \delta^{(3)}(x - x^{(i)}) K(\eta)L^{(i)}(\eta), \]  

(2.9)

where the luminosity of the \( i \)-th source is defined by

\[ L^{(i)}(\eta) = \int_{\nu_1}^{\nu_2} d\nu L_{\nu}^{(i)}(\eta), \]  

(2.10)

and \( K(\eta) \) is defined by

\[ K(\eta) = \frac{1}{L^{(i)}(\eta)} \int_{\nu_1}^{\nu_2} d\nu_0 L_{\nu \rightarrow \nu_0/a}^{(i)}(\eta), \]  

(2.11)

then by integrating (2.9), we get

\[ I(\eta_0, x_0, \gamma) = \frac{1}{4\pi} \sum_i \int d\eta a(\eta) K(\eta)L^{(i)}(\eta)\delta^{(3)}(x(\eta, \gamma) - x^{(i)}), \]  

(2.12)

where \( x(\eta, \gamma) \) stands for a photon path.

Because \( \sum_i \delta^{(3)}(x - x^{(i)}) \) is regarded as a number density field and we replace it with

\[ \sum_i \delta^{(3)}(x - x^{(i)}) \Rightarrow \int d\log L(\eta, x), \]  

(2.13)

\[ K(\eta)/a(\eta) \] denotes the usual K-correction.
where \(n(L, \eta, x)\) is the luminosity function which denotes a number of sources per unit comoving volume and per unit log\(L\). Then we rewrite (2.12) as

\[
I(\eta_0, x_0, \gamma) = \frac{1}{4\pi} \int d\log LL \int d\eta a(\eta) K(L, \eta)n(L, \eta, x(\eta, \gamma)), \tag{2.14}
\]

where \(K(L, \eta)\) is defined for a source with luminosity \(L\) in same way as (2.11).

Here we mention the range of \(\eta\) integration in equation (2.14). The range of \(\eta\) integration depends on observational situation and strategy. In this paper we focus on background fluctuations. In order to reduce the shot noise fluctuations, which are described later in this paper, we assume that bright nearby sources are removed from an observed map. Darker and darker sources we get rid of, more and more distant sources are removed. This flux cutoff limit is denoted by \(S_c\). The local luminosity of a source \(L\) is related with the observed flux \(S\) and the distance, which we describe by the conformal time \(\eta\) in stead of the redshift, as

\[
S = \frac{aLK(L, \eta)}{4\pi D(\eta)^2}, \tag{2.15}
\]

where \(D(\eta) = (-K)^{-1/2}\sinh(\sqrt{-K}(\eta_0 - \eta))\) and \(\eta_0\) is the conformal time at the present epoch. Note that the distance \(D\) is related with the luminosity distance \(d_L\) by \(D(\eta) = d_L/(1 + z)\) [13]. In case of observations with the flux cutoff limit \(S_c\), the range of \(\eta\) integration must be \(0 \leq \eta \leq \eta_c\), where \(\eta_c\) is determined by solving (2.14) with setting \(S = S_c\). Thus \(\eta_c\) is a function of \(L\) and \(S_c\), in general. As we will see in the next section, the removal of bright sources is an important factor in predicting the fluctuations.

In order to discuss statistics of the fluctuations we define the angular two-point correlation function:

\[
C(\theta) = \int \int d\Omega_1' d\Omega_2' \frac{1}{2\pi} \delta(\gamma_1' \cdot \gamma_2' - \cos \theta) I(\eta_0, x_0, \gamma_1') I(\eta_0, x_0, \gamma_2') = \int \int d\Omega_1' d\Omega_2' \frac{1}{2\pi} \delta(\gamma_1' \cdot \gamma_2' - \cos \theta)
\]

\[
\times \frac{1}{4\pi} \int d\log L_1 L_1 \int_0^{\eta_c} d\eta_1 a_1 K(L_1, \eta_1) n(L_1, \eta_1, x(\eta_1, \gamma_1')) \]

\[
\times \frac{1}{4\pi} \int d\log L_2 L_2 \int_0^{\eta_c} d\eta_2 a_2 K(L_2, \eta_2) n(L_2, \eta_2, x(\eta_2, \gamma_2')) \tag{2.16}
\]

where \(a_1 = a(\eta_1)\) and \(a_2 = a(\eta_2)\).

Theoretically we can only predict the ensemble average of fluctuations. To obtain the ensemble average of the two-point correlation function, we need the ensemble average \(\langle n(L_1, \eta_1, x_1)n(L_2, \eta_2, x_2) \rangle\) from equation (2.16). In case of point-like sources, it is well known that the ensemble average of a product of the density field has three terms, i.e., homogeneous term, clustering term and shot term [14, 15]. As we are dealing with the density field as a function of luminosity and time, the relation \(\langle n(L_1, \eta_1, x_1)n(L_2, \eta_2, x_2) \rangle\) is not trivial in a strictly sense. However, assuming that the luminosity of sources is statistically independent of their positions relative to the other sources, we set the following relation [12, 13]:

\[
\langle n(L_1, \eta_1, x_1)n(L_2, \eta_2, x_2) \rangle = \bar{n}(L_1, \eta_1)\bar{n}(L_2, \eta_2) + \bar{n}(L_1, \eta_1)\bar{n}(L_2, \eta_2)\xi(\eta_1, \eta_2; x_1 - x_2)
\]

\[
+\bar{n}(L_1, \eta_1)\delta(\log L_1 - \log L_2)\delta^{(3)}(x_1 - x_2), \tag{2.17}
\]

where \(\bar{n}(L, \eta)\) is the spatially averaged quantity of \(n(L, \eta, x)\). The first term of r.h.s. of (2.17) is the isotropic background component, the second term describes the clustering of the sources, the third term is called the shot term, which arises from the discreteness of the sources [15]. Then the ensemble average \(\langle C(\theta) \rangle\) has three terms, i.e., isotropic background term, clustering term and shot noise term, which we write as \(\langle C(\theta) \rangle = \langle C_{ISO}(\theta) \rangle + \langle C_{CL}(\theta) \rangle + \langle C_{SN}(\theta) \rangle\).
A. Isotropic background

First we consider the isotropic background term. From (2.16) and the first term of r.h.s. of (2.17), we easily get
\[ \langle C^{ISO} \rangle = \left( \frac{1}{4\pi} \int d\log LL \int_0^{\eta_c} d\eta aK(L, \eta) \bar{n}(L, \eta) \right)^2 = \left( f^{(0)} \right)^2, \] (2.18)
where we used
\[ \int \int \frac{d\Omega_1}{4\pi} \frac{d\Omega_2}{2\pi} \delta(\vec{\gamma}_1 \cdot \vec{\gamma}_2 - \cos \theta) = 1. \] (2.19)

B. Fluctuations from Source Clustering

The correlation function of the source clustering term is
\[ \langle C(\theta) \rangle^{CL} = \int \int \frac{d\Omega_1}{4\pi} \frac{d\Omega_2}{2\pi} \delta(\vec{\gamma}_1 \cdot \vec{\gamma}_2 - \cos \theta) \]
\[ \times \frac{1}{4\pi} \int d\log L_1 L_1 \int_0^{\eta_c} d\eta_1 a_1 K(L_1, \eta_1) \bar{n}(L_1, \eta_1) \]
\[ \times \frac{1}{4\pi} \int d\log L_2 L_2 \int_0^{\eta_c} d\eta_2 a_2 K(L_2, \eta_2) \bar{n}(L_2, \eta_2) \]
\[ \times \xi(\eta_1, \eta_2; \vec{x}_1(\eta_1, \vec{\gamma}_1) - \vec{x}_2(\eta_2, \vec{\gamma}_2)). \] (2.20)

To relate the correlation function of X-ray sources with that of CDM, we write
\[ \xi(\eta_1, \eta_2; \vec{x}_1 - \vec{x}_2) = b_X(\eta_1) b_X(\eta_2) \xi(\eta_1, \eta_2; \vec{x}_1 - \vec{x}_2)_{CDM}, \] (2.21)
where \( b_X(\eta) \) is the bias factor\(^\dagger\), the CDM density correlation function is \( \xi(\eta_1, \eta_2; \vec{x}_1 - \vec{x}_2)_{CDM} = \langle \delta_c(\eta_1, \vec{x}_1) \delta_c(\eta_2, \vec{x}_2) \rangle \), and \( \delta_c(\eta, \vec{x}) \) is the CDM density contrast. While the nonlinearity of the CDM density contrast may be effective, however, we only consider linear theory in this paper. In this case \( \xi(\eta_1, \eta_2; \vec{x}_1 - \vec{x}_2)_{CDM} \) is proportional to \( D_1(\eta_1)D_1(\eta_2) \), where \( D_1(\eta) \) is the linear growth rate normalized to unity at present.

We next consider to express the CDM density contrast in terms of the density power spectrum. In order to express Gaussian random process of the CDM density field, we introduce probability variables \( a_{\omega lm} \), which satisfy,
\[ \langle a_{\omega lm} \rangle = 0, \quad \langle a_{\omega lm} a_{\omega' l'm'}^* \rangle = \delta(\omega - \omega') \delta_{ll'} \delta_{mm'}. \] (2.22)
For the condition of reality of density field we assume \( a_{\omega lm}^* = a_{\omega l m} \). Then we can write the CDM density fluctuation fields as
\[ \delta_c(\eta, \vec{x}) = \int_0^{\infty} d\omega \sum_{lm} a_{\omega lm} \delta_\omega(\eta) \psi_{\omega lm}(\vec{x}), \] (2.23)
\[ ^\dagger \] The bias factor could be a function of luminosity \( L \) in general. However we ignore the dependence of luminosity for simplicity.
where $\delta_c(\eta)$ is the root-mean-square of the coefficient associated with the orthonormalized harmonics in the hyperbolic universe

$$\mathcal{Y}_{\omega lm}(x) = (-K)^{3/4} W_{\omega l}(\chi) Y_{lm}(\Omega)$$

$$= (-K)^{3/4} \frac{\Gamma(i\omega + l + 1)}{\Gamma(i\omega)} P_{l-1/2}^{-1/2}(\cosh \chi) Y_{lm}(\Omega),$$

which satisfies

$$\int (-K)^{-3/2} \sinh^2 \chi d\chi d\Omega \mathcal{Y}_{\omega lm}(\chi, \Omega) \mathcal{Y}_{\omega' l'm'}^*(\chi, \Omega) = \delta(\omega - \omega') \delta_{ll'} \delta_{mm'},$$

where $\Gamma(z)$ is the Gamma function and $P^\mu_r(z)$ is the Legendre function. Here $\omega$ is a non-dimensional wave number and $K(\omega^2 + 1)$ is the eigen-value of the scalar harmonics $\mathcal{Y}_{\omega lm}(x)$ in the hyperbolic universe \[2.4\] \[21\] \[23\]. Then we have

$$\langle \delta_c(\eta_1, x_1) \delta_c(\eta_2, x_2) \rangle = \sum_{lm} \int \delta_\omega(\eta_1) \mathcal{Y}_{\omega lm}(\chi_1, \Omega_1) \delta_\omega(\eta_2) \mathcal{Y}_{\omega lm}(\chi_2, \Omega_2).$$

From a straightforward calculation using the relations

$$\delta(\vec{\gamma}_1 \cdot \vec{\gamma}_2 - \cos \theta) = \sum_{l=0}^{2l+1} \frac{2l+1}{2} P_l(\vec{\gamma}_1 \cdot \vec{\gamma}_2) P_l(\cos \theta),$$

$$P_l(\vec{\gamma}_1 \cdot \vec{\gamma}_2) = \frac{4\pi}{2l+1} \sum_{m=-l}^{l} Y_{lm}(\Omega_\gamma_1) Y_{lm}^*(\Omega_\gamma_2),$$

where $Y_{lm}(\Omega_\gamma)$ is the spherical harmonics in an unit sphere, equation \[2.26\] reduces to

$$\langle C(\theta)^{CL} \rangle = \sum_{l} \frac{2l+1}{4\pi} C_{l}^{CL} P_l(\cos \theta),$$

with

$$C_{l}^{CL} = \int \delta_\omega(\eta) \mathcal{Y}_{\omega lm}^*(\chi_\eta) \mathcal{Y}_{\omega lm}(\chi_\eta) \mathcal{Y}_{\omega lm}(\chi_\eta) W_{\omega l}(\Delta \eta)^2,$$

where $\Delta \eta = \sqrt{-K}(\eta_0 - \eta)$ and $W_{\omega l}(\chi)$ is defined in equation \[2.24\]. This expression is rewritten as

$$C_{l}^{CL} = \frac{2}{\pi} \int \delta_\omega(\eta) \mathcal{Y}_{\omega lm}^*(\chi_\eta) \mathcal{Y}_{\omega lm}(\chi_\eta) X_{\omega l}(\Delta \eta)^2,$$

where $M_l = (\hat{k}^2 - K) \cdots (\hat{k}^2 - l^2 K) / (\hat{k}^2 - K)^l$, $\hat{k} = \sqrt{-K} \omega$, and

$$X_{\omega l}(\chi) = \left( \frac{\pi(\omega^2 + 1)^l}{2} \right)^{1/2} \frac{P_{l-1/2}^{-1/2}(\cosh \chi)}{\sqrt{\sinh \chi}}.$$

In the limit of flat universe, i.e., $K \to 0$, the function $X_{\omega l}(\chi)$ reduces to the spherical Bessel function \[21\] \[23\].

\[\dagger\] Throughout this paper we consider an ideal detector with infinite small angular resolution. The effect of a finite beam width and a limited observational area can be taken into account by multiplying a window function in the similar way as the case of CMB temperature anisotropies.
C. Random Fluctuations

Finally we consider random fluctuations from the shot term. The ensemble average of the two-point correlation function is

\[
\langle C(\theta)^{\text{SN}} \rangle = \int \int \frac{d\Omega_{1}}{4\pi} \frac{d\Omega_{2}}{2\pi} \delta(\vec{\gamma}_{1} \cdot \vec{\gamma}_{2} - \cos \theta) \times \frac{1}{4\pi} \int d\log L_{1} \int_{0}^{\eta_{1}} d\eta_{1} a_{1} K(L_{1}, \eta_{1}) \frac{1}{4\pi} \int d\log L_{2} \int_{0}^{\eta_{2}} d\eta_{2} a_{2} K(L_{2}, \eta_{2}) \times \bar{n}(L_{1}, \eta_{1}) \delta(L_{1} - L_{2}) \delta(3)(x_{1}(\eta_{1}, \vec{\gamma}_{1}) - x_{2}(\eta_{2}, \vec{\gamma}_{2})).
\]

As the delta function is expressed

\[
\delta(3)(x_{1} - x_{2}) = (-K)^{3/2} \frac{\delta(\chi_{1} - \chi_{2})}{\sinh^{2} \chi_{1}} \delta(2)(\vec{\gamma}_{1} - \vec{\gamma}_{2}),
\]

then equation (2.33) leads to

\[
C^{\text{SN}}(\theta) = \sum_{l} \frac{2l + 1}{4\pi} C_{l}^{\text{SN}} P_{l}(\cos \theta),
\]

with

\[
C_{l}^{\text{SN}} = \int d\log L L^{2} \int_{0}^{\eta} d\eta \left( \frac{1}{4\pi} a K(L, \eta) \right)^{2} \bar{n}(L, a) \frac{-K}{\sinh^{2} \Delta \eta},
\]

where \( \Delta \eta = \sqrt{-K(\eta_{0} - \eta)} \). Here we used equations (2.27) and (2.28). This spectrum is independent of \( l \), which implies that this fluctuation is a white noise type. And this means \( \langle C(\theta)^{\text{SN}} \rangle \propto \delta(\theta) \).

III. FLUCTUATIONS IN A SIMPLE MODEL

In this section we discuss characteristic behavior of fluctuations by considering a simple evolution model of X-ray sources. The evolution and population of X-ray sources at high redshift are less well understood. Here we consider a model of a single class of sources, i.e., the case that the sources have same luminosity profile at a cosmic time. In this case the luminosity function is given by

\[
\bar{n}(L, \eta) = \bar{n}(a) \delta(\log L - \log \mathcal{L}),
\]

where \( \mathcal{L} \) is the luminosity of a source and \( \bar{n} \) is the averaged number density of sources. We assume that the sources are distributed to the redshift \( z_{\text{max}} \). Furthermore we assume power-law evolution of the source number density and the luminosity:

\[
\bar{n}(a) = n_{0} a^{-d}, \quad \mathcal{L} = L_{0} a^{-e},
\]

where \( n_{0} \) and \( L_{0} \) are constants. We further assume the power-law frequency dependence \( L_{\nu} \propto \nu^{-\alpha} \), then we have

\[
K(L, \eta) = a(\eta)^{\alpha}.
\]

As for the bias, we take into account the epoch-dependent bias by setting

\[
b_{X}(\eta) = b_{X0} + z[b_{X0} - 1],
\]

where \( z \) is the redshift and \( b_{X0} \) is a constant. Although this simple formula might be applicable only in the Einstein de Sitter universe, we use it even for other cosmological models for simplicity.
A. Fluctuations from Source Clustering

The above simplification leads to the following simple expressions for the isotropic background and the angular power spectrum of source clustering:

\[ I^{(0)} = \frac{n_0 L_0}{4\pi} \int_{\eta_0}^{\eta_c} d\eta \eta^{1-d-\epsilon+\alpha}, \]  

\[ C^\text{CL}_l = \frac{2}{\pi} \int_0^{\infty} d\tilde{k} \tilde{k}^2 M_l \left( \frac{n_0 L_0}{4\pi} \int_{\eta_0}^{\eta_c} d\eta \eta^{1-d-\epsilon+\alpha} b_X(\eta) \delta_\omega(\eta) X_l^I(\Delta \eta) \right)^2, \]  

where \( \eta \) is the conformal time at the redshift \( z_{\text{max}} \). Note also that the relative amplitude of fluctuations \( C^\text{CL}_l/(I^{(0)})^2 \) is independent of \( n_0 L_0 \). The evolution of the X-ray sources are less understood. Let us consider the case that the volume emissivity evolves with the time, and we set \( p = d + \epsilon = 3 \) for simplicity. We adopt this value and \( \alpha = 0.4 \) in the rest of this paper.

The angular power spectrum is shown in Figure 1 for various cosmological models. In Fig.1(a) and 1(b), the three panels correspond to the different cosmological models, a ‘standard’ CDM model (SCDM), a CDM model with the cosmological constant (ΛCDM) and an open CDM model (OCDM). In each panel three lines stand for the different parameters for removal of bright sources. For simplicity we take this effect into account by specifying the distance of redshift \( z_{\text{min}} \) instead of specifying \( S_c \). We assumed that the sources of \( 0 \leq z \leq z_{\text{min}} \) were removed. In the figure three lines correspond to the cases \( z_{\text{min}} = 0, 0.02, 0.1, \) Fig.1(a) is the case of no bias by setting \( b_{X0} = 1 \) in equation (3.4). In Fig.1(b) we chose \( b_{X0} = 1.6 \) as a case of the epoch-dependent bias, where the bias factor becomes significant at \( z \gtrsim 1 \). The CDM density power spectrum is normalized as \( \sigma_8 = 1 \).

First notable feature is that the amplitude of fluctuations strongly depends on \( z_{\text{min}} \) for low multipoles, i.e., large-angle scales. As \( z_{\text{min}} \) controls distance to which nearby sources are removed, the decrease of the low multipoles is due to the removal of the sources. This implies that the nearby sources dominantly contribute to the low multipoles. On the contrary, the high multipoles do not depend on \( z_{\text{min}} \).

In order to understand the evolution of the amplitude of fluctuations in more detail, we show the amplitude of the multipoles \( l = 1, 10, 30, 100 \), as a function of \( z_{\text{min}} \) in Fig.2. The large value of \( z_{\text{min}} \) in this figure might be unrealistic from the observational view point for an all sky survey. However this figure is instructive to understand what sources are dominant contributors to the fluctuations of each angular size. The steep decrease of the low multipole at \( z_{\text{min}} \lesssim 0.1 \) indicates that low redshift sources sensitively contribute to the large-angle fluctuations. On the other hand the higher multipole \( (l = 100) \) does not sensitively depend on \( z_{\text{min}} \) and it is not almost affected by the removal of the sources for \( z_{\text{min}} \lesssim 2 \). This means that the high redshift sources of \( z \gtrsim 1 \) are the dominant contributors to the small-scale fluctuations \( l \gtrsim 100 \). It is shown that the amplitude of the fluctuations increase for \( z_{\text{min}} \gtrsim 2 \). This effect makes the amplitude of the fluctuations increase since the fluctuations suffer less significant thickness damping, that is contributions from sources at different redshifts cause the cancellation. We think that the increase of the fluctuations at \( z_{\text{min}} \gtrsim 2 \) in Fig.2 due to this effect.

Comparing Fig.1(a) and 1(b), evolution of the bias derives significant difference on small scales. For the low multipoles, since the nearby sources of low redshift dominantly contribute to the fluctuations, the (low multipole) amplitude scales by the bias factor at present epoch \( b_{X0} \). However the amplitude on small scales is significantly increased for the epoch-dependent bias model. This is understood that the high redshift sources are the dominant contributors to the small-angle fluctuations and the amplitude is increased due to the large value of the bias factor at high redshift.

It is notable that the dependence on the cosmological models is quite weak even on small scales. Because we have employed \( \sigma_8 \) normalization, the shape of the density power spectrum of the OCDM model is almost same as the ΛCDM model. The difference between these two models is small at a few\%×10\% level. However the amplitude of fluctuations of the OCDM model is slightly larger than the Λ model on small scales. This would be understood as follows. When we see a same physical size in the open universe, the
angle size becomes smaller compared with the case of the flat universe due to the curvature of background geometry. Therefore the large-scale fluctuations in the open model shift to the smaller scale. This is the same situation as the case of CMB anisotropies.

**B. Shot Noise v.s. Source Clustering**

In this subsection we discuss the shot noise fluctuations comparing them with the fluctuations due to the source clustering. The shot noise fluctuations are random fluctuations originated from discreteness of the sources. The spectrum is the white noise type and the angular power spectrum does not depend on $l$. In our simple model, equation (2.36) reduces to

$$C_{i}^{SN} = \frac{n_0 L_0^2}{(4\pi)^2} \int_{\eta_i}^{\eta_c} d\eta \left( a^{1-\epsilon+\alpha} \right) a^{-d} \frac{-K}{\sinh^2 \Delta \eta}. \tag{3.7}$$

Assuming $\eta_c \simeq \eta_0$ and $(\eta_0 - \eta_c)/\eta_0 \ll 1$, we approximately rewrite it as

$$C_{i}^{SN} \simeq \frac{n_0 L_0^2}{(4\pi)^2} \int_{\eta_i}^{\eta_c} d\eta \frac{\eta}{(\eta_0 - \eta)} \simeq \frac{n_0 L_0^2}{(4\pi)^2} \frac{1}{\eta_0 - \eta_c}, \tag{3.8}$$

$$S_c \simeq \frac{L_0}{4\pi(\eta_0 - \eta_c)^2}, \tag{3.9}$$

where the second equation is derived from (2.15). Then we have

$$C_{i}^{SN} \simeq S_c^{1/2} n_0 \left( \frac{L_0}{4\pi} \right)^{3/2}. \tag{3.10}$$

This approximation is valid for the case that the removed bright sources are located at low redshift $z \ll 1$. Using the value $I^{(0)} = 5.2 \times 10^{-8}$ erg s$^{-1}$ cm$^{-2}$ str$^{-1}$ in 2 − 10 keV band [23], we have

$$\sqrt{\frac{C_{i}^{SN}}{I^{(0)}}} = 1.2 \left( \frac{S_c}{\text{erg s}^{-1} \text{cm}^{-2}} \right)^{1/4} \left( \frac{L_0}{3 \times 10^{43} \text{erg s}^{-1}} \right)^{3/4} \left( \frac{n_0}{3 \times 10^{-5} \text{Mpc}^{-3}} \right)^{1/2}. \tag{3.11}$$

From (3.3) and $\eta_0 - \eta \simeq z/H_0$, which is obtained from the Friedmann equation, we estimate the redshift $z_{\text{min}}$ to which the bright sources are removed as

$$z_{\text{min}} \simeq \left( \frac{L_0 H_0^2}{S_c} \right)^{1/2} \simeq 0.03 h \left( \frac{L_0}{3 \times 10^{43} \text{erg s}^{-1}} \right)^{1/2} \left( \frac{S_c}{3 \times 10^{-11} \text{erg s}^{-1} \text{cm}^{-2}} \right)^{-1/2}. \tag{3.12}$$

As we see from (3.10), the shot noise fluctuations are controlled by the flux cutoff limit $S_c$. When $S_c$ is decreased the shot noise fluctuations reduce too. As we saw in the previous subsection, the amplitude of the low multipole fluctuations due to the source clustering decreases when $S_c$ is decreased. However, the higher multipoles are constant even when $S_c$ is decreased. The epoch-dependence of the bias factor makes the amplitude of small-scale fluctuations significant. Now let us compare these two fluctuations, the source clustering and the shot noise. In Fig.3 the fluctuations due to source clustering are compared with the shot noise fluctuations as a function of $S_c$. In this figure we focused on the multipole of $l = 100$. The upper panel is the case of no bias by setting $b_{X0} = 1$ in equation (3.4). In the lower panel we chose $b_{X0} = 1.6$. The large difference between these two panels, which is due to the high bias factor at high redshift, implies that the bias is a very important factor besides the evolution of the luminosity function of sources when predicting the fluctuations due to source clustering.
IV. SUMMARY AND DISCUSSION

In this paper we have formulated equations to investigate the X-ray background fluctuations in various cosmological models in a systematic way. We have made full use of the harmonic expansion method in terms of multipole components in both open (hyperbolic) and flat universes to obtain the angular power spectrum of fluctuations. The fluctuations due to the source clustering and the shot noise can be predicted if the evolution of the luminosity function and the bias factor are given. We have calculated the angular power spectrum for the X-ray background fluctuations in various cosmological models based on a simple X-ray source model. As Lahav, et al. pointed out [2], the fluctuations predicted in the simple model strongly depend on the evolution parameter of sources, and rather weakly depend on the cosmological models. Moreover, the large-angle (low multipole of $l \lesssim 10$) fluctuations are strongly affected by the flux cutoff parameter for removal of nearby bright sources [15,2]. This is because the nearby sources of low redshift are the dominant contributors to the large-angle fluctuations. Therefore, when one makes the comparison between the theoretical prediction and the observational data on large angular scales, the procedure of removing bright sources has to be very carefully taken into account.

In this paper, we have developed the formulation which is useful to calculate the angular power spectrum. In the observational point of view, however, we may not have to derive $C_\ell$ in small scales [11]. The description by $\langle C(\theta) \rangle$ is usually used when one compares the theoretical prediction with observational data (e.g., [13]). Of course, we can easily derive $\langle C(\theta) \rangle$ from $C_\ell$ by equation (2.29) with a window function. Moreover, our approach is useful to understand the physical mechanism which determines the behaviors of fluctuations on various scales. This formulation is not limited to the X-ray background fluctuations but it can be easily generalized to calculate the clustering of point-like sources at high redshift.

In predicting the X-ray background fluctuations the evolution of luminosity function is an important factor. Our analysis shows that the evolution of the bias factor is also a very important factor especially on small scales. This is because the small-scale fluctuations contain information of clustering in the high redshift universe. In order to use the X-ray background fluctuations as a probe of large scale cosmological density fluctuations at high redshift, the knowledge of the evolution of the bias factor and the luminosity function is necessary factor, because the dependence of cosmology on the X-ray background fluctuations is rather weak. Conversely, which suggests that the X-ray background is a good probe for the bias mechanism of high redshift sources [27,28] when the cosmological parameters are fixed. The future X-ray mission projects will give us fine solution for the evolution of X-ray sources. In that case the X-ray background will be a possible probe to investigate the clustering and formation process of X-ray sources in the high redshift universe.

ACKNOWLEDGMENT

One of the authors (K.Y.) thanks Prof. Y.Kojima for comments and encouragement. He is grateful to Prof. K.Tomita and J.Yokoyama and people in Yukawa Institute for Theoretical Physics, Kyoto university, where part of the work was done. He also thanks Prof. Y.Suto, N.Gouda and O.Lahav for useful comments and discussions. We acknowledge helpful conversations on the subject of this paper with Prof. M.Sasaki, K.Mitsuda, T.Matsubara, T.Ohsugi, N.Sugiura and Y.Miura. FIGURE CAPTION

Fig. 1— The angular power spectrum of fluctuations due to source clustering for various cosmological models. The cosmological parameters are taken as $h = 0.5$ and $\Omega_0 = 1$ for the SCDM model, and $h = 0.7$ and $\Omega_0 = 0.3$ for the $\Lambda$CDM and OCDM models. The parameters $p = d + e = 3$ and $z_{\text{max}} = 3$ are taken. In each panels three lines correspond to $z_{\text{min}} = 0$, 0.02, 0.1, respectively. Fig.1(a) is the case of no bias by setting $b_{X0} = 1$ in equation (3.4). In Fig.1(b) $b_{X0} = 1.6$ is chosen as a case of epoch-dependent bias. Note that the area under the lines do not directly describe the amount of observed fluctuations since $\sqrt{\ell(2\ell+1)C_\ell}$ is the one in case of the logarithmic interval of x-axis (see Eq. 2.29). Roughly speaking, we need to multiply $\ell$. Therefore there are larger fluctuations on smaller scales. On the other hand, the contribution from the shot noise does not depend on $\ell$ in these figures.

Fig. 2— $z_{\text{min}}$ dependence of multipoles for the $\Lambda$CDM model. The four panels correspond to the multipoles $l = 1$, 10, 30, 100, respectively. The solid line represents the case $b_{X0} = 1$ and the dashed line does the case $b_{X0} = 1.6$. The model parameters are same as that in Fig.1(a).

Fig. 3— Comparison of fluctuations due to source clustering and shot noise term as a function of flux cutoff limit $S_c$. The upper panel is the case of no bias by setting $b_{X0} = 1$ in equation (3.4). In the lower panel $b_{X0} = 1.6$ is chosen as a case of epoch-dependent bias. Each panel shows the multipole $l = 100$. The solid line shows the clustering fluctuations and the dashed line does the shot noise fluctuations. For the clustering fluctuations we used the SCDM model with $h = 0.5$ and $\Omega_0 = 1$. Here we normalized the CDM density fluctuations by $\sigma_8 = 0.5$. In order to calculate the shot noise term, we need to specify the values of $e$ and $d$, separately. Though there are many uncertainties in the evolution model of the sources, let us take the values $e = 1.4$ and $d = 1.6$. In this case we have $1 + \alpha - e = 0$, which allow us some analytic calculations when solving equation (2.17). We also used the parameters $L_0 = 3 \times 10^{43}\text{erg/s}$, $n_0 = 10^{-5}/\text{Mpc}^3$. We set $z_{\text{max}} = 3.2$ in order to be $I^{(0)} = 5.2 \times 10^{-5}\text{erg/s/cm}^2$. In this case of the parameters the estimation for the shot noise fluctuation is $\sqrt{C^\text{SN}_\ell/I^{(0)}} \approx 0.7S_c^{-1/4}/(\text{erg/s/cm}^2)$. The dashed line shows the result obtained by calculating Eq.(3.7). The dotted line is the result obtained by extrapolating the estimation by Lahav et al. [2].
