Abstract. Background/Aim: The present study aimed to compare the radiation dose distribution of carbon-ion radiotherapy (CIRT) for stage I esophageal cancer with three-dimensional conformal radiotherapy (3DCRT) and volumetric modulated arc therapy (VMAT). Patients and Methods: Fifteen patients with cT1bN0M0 esophageal cancer who received 3DCRT at Kanagawa Cancer Center between January 2014 and April 2019 were enrolled. The dose-volume histogram parameters of the target volume and normal organs planned with CIRT, 3DCRT, and VMAT were evaluated. Results: The homogeneity index for the target volume of CIRT was significantly lower than that of 3DCRT and VMAT. In addition, the radiation dose of CIRT to the heart, lungs, spinal cord, and skin was significantly lower than that of 3DCRT and VMAT. Conclusion: Favorable dose distributions with CIRT were demonstrated compared with 3DCRT and VMAT for esophageal cancer.

One of the radical treatments for stage I esophageal cancer is radiotherapy (1). Favorable clinical outcomes have been reported for radiotherapy for esophageal cancer (1). However, treatment-related late toxicities have been recently reported when long-term survival was achieved through radiotherapy (2). Late toxicities to the heart and lungs following radiotherapy could be particularly problematic and could even be fatal (2-4). Various technologies of radiotherapy, such as intensity-modulated radiotherapy (IMRT) and particle beam radiotherapy, have been developed to reduce the radiation dose to the normal organs.

Carbon-ion radiotherapy (CIRT) was developed in 1994 by the National Institute of Radiological Sciences (Chiba, Japan) (5). CIRT has significant more physical and biological advantages compared to conventional radiation therapy using X-rays (XRT). CIRT exhibits higher radiation dose concentration and better dose distribution due to the Bragg peak and sharp penumbra, with regards to the physical aspects (6). Furthermore, with regard to the biological characteristics, the biological effect of CIRT is approximately three-fold higher than that of XRT (7, 8). These characteristics offer a good therapeutic outcome without severe adverse events in normal tissue. In fact, favorable clinical outcomes with CIRT have been reported for various diseases (9-11).

At Kanagawa Cancer Center (KCC), CIRT was initiated in 2015 (12). CIRT was administered using the raster scanning method in all cases at KCC. The raster scanning method involves scanning with a pencil beam of ~3 mm in diameter, at high speed. This method, coupled with the high speed irradiates the target in a three-dimensional manner and enables radiation dose distribution with greater concentration compared to the conventional broad beam method (13). Favorable clinical outcomes have been reported with CIRT for prostate cancer at KCC (14).

Proton beam therapy (PBT) has a similar Bragg peak as CIRT, resulting in high radiation dose concentration (15). For esophageal cancer, PBT has been found to show better radiation dose distribution compared to XRT (15-17). However, no studies have compared the radiation dose distribution of CIRT and that of XRT. Therefore, in the present study, quantitative analysis was conducted to compare the radiation dose distribution of CIRT for stage I esophageal cancer with three-dimensional conformal radiotherapy (3DCRT) and volumetric modulated arc therapy (VMAT).
Patients and Methods

Patients. The hospital institutional review board approved this study (approval number: 2020-71). The subject sample included patients with cT1bN0M0 esophageal cancer who received radiotherapy delivered by 3D CRT between January 2014 and April 2019 at KCC. From the most recent cases, we included five cases of the upper thoracic area (UT), midthoracic area (MT), and lower thoracic area (LT) for a total of 15 cases as the tumor site affects the radiation dose distribution on normal tissue (15, 18).

Treatment planning. Computed tomography (CT) scans were performed in 2.5-5 mm slices with free breathing. Gross tumor volume (GTV) was identified using a clip that was placed endoscopically in advance. Clinical target volume (CTV) 1 included the lymph node regions by tumor location as follows: UT esophageal cancer included the supraclavicular and superior mediastinal lymph node regions, MT esophageal cancer included the superior and inferior mediastinal lymph node regions and intra-abdominal lymph node regions, and LT esophageal cancer included the inferior mediastinal and intra-abdominal lymph node regions. CTV2 extended 2 cm in each longitudinal direction of the esophagus from the GTV. Planning target volume (PTV) 1 and 2 were CTV 1 and 2+5 mm in all directions, respectively. The heart, lungs, spinal cord, and skin were extracted as organs at risk (OAR). OAR was extracted according to the RTOG1106 OAR atlas (19). The radiation dose for the skin was evaluated upon creating an inner ring structure of 0.2 mm in thickness from the auto-extracted skin (20). The same structure was used for CIRT, 3D CRT, and VMAT planning.

The dose of CIRT is expressed as Gy [relative biological effectiveness (RBE)], which is defined as the physical dose multiplied by the RBE of the carbon ions. The prescribed radiation dose was 41.4 Gy in XRT or Gy (RBE) in CIRT for PTV1 and an additional 9.0 Gy or Gy (RBE) for PTV2. The total dose for PTV2 was 50.4 Gy or Gy (RBE). In 3D CRT, an anteroposterior opposing portal beam was set at 41.4 Gy, and the spinal cord was shielded by irradiating at 9.0 Gy with an oblique opposing beam. The same beam placement was used for CIRT. For 3D CRT, the radiation dose was prescribed to the isocenter, and a plan was created to cover the CTV with 95% of the radiation dose. For VMAT, the radiation dose was prescribed to be the mean radiation dose (Dmean) of PTV2. CIRT treatment plan was created to cover 95% of the PTV with 95% of the prescription dose. The dose constraints for OARs were as follows: The maximum dose (Dmax) was 45 Gy or Gy (RBE) for the spinal cord, and V20 ≤20% for the lungs. Treatment plans were created with the Monaco version 5.11 (Elekta AB, Stockholm, Sweden) for 3D CRT and VMAT, and treatment plans for CIRT were created with the Monaco version 5.20 for carbon-ion scanning (Elekta AB). All treatment plans were transferred to the MIM maestro software version 6.9 (MIM Software Inc., Cleveland, OH, USA), and dose-volume histograms (DVH) were created. The following DVH parameters were assessed: the dose covering 98% of the target volume (D98), D95, D50, D2, and the homogeneity index (HI) for PTVs. HI was calculated by (D2-D98)/D50 (21). V10-50 and D mean for the heart, with V5-V50 and Dmean for the lungs, Dmax for the spinal cord, and Dmax for the skin were also evaluated.

Statistical analysis. The DVH parameters of each treatment method were compared using the Wilcoxon matched-pairs test. For CIRT, DVH parameters were compared according to each tumor site using Mann-Whitney U-test. A p-value of <0.05 was considered statistically significant. Statistical analyses were conducted using STATA software (version 13.1, College Station, TX, USA).

Results

PTV. Typical radiation dose distribution and DVH are presented in Figure 1. The DVH parameters for PTVs are summarized in Table I. There was no significant difference in D50 of PTV2 with CIRT compared with 3D CRT and VMAT (p=0.477, 0.172). In CIRT, the D98 of PTV2 was significantly higher than that in 3D CRT and VMAT, whereas D2 was significantly lower. The HI was 0.02±0.01, 0.07±0.02, and 0.07±0.02 in CIRT, 3D CRT, and VMAT, respectively. HI of CIRT was significantly lower than that of 3D CRT and VMAT (p<0.001 and p<0.001, respectively).

OARs. The DVH parameters for OARs are presented in Table II. All the CIRT domestic variables regarding the heart

Figure 1. Comparison of a typical radiation dose distribution. For PTV1, 41.4 Gy or Gy (RBE) was administered. For PTV2, a total dose of 50.4 Gy or Gy (RBE) was administered. (a) Radiation dose distribution of CIRT, 3D CRT, and VMAT. (b) DVH of CIRT, 3D CRT, and VMAT.
dose were significantly lower than those of the 3DCRT plans. All the CIRT domestic variables regarding the heart dose, except for the V50, were significantly lower than those of the VMAT plans. The Dmean of the heart was 9.6±4.5 Gy (RBE) for CIRT compared with 29.1±11.7 Gy for 3DCRT and 22.3±9.0 Gy for VMAT, indicating a significant difference (p<0.001 and p<0.001, respectively). All the CIRT domestic variables regarding the lung dose were significantly lower than those of the 3DCRT plans. All the CIRT domestic variables regarding the lung dose except for the V50 were significantly lower than those of the VMAT plans. The Dmean of the lungs was 1.8±0.9 Gy (RBE) for CIRT, as compared to 5.3±1.8 Gy in 3DCRT, and 11.4±2.3 Gy in VMAT, indicating a significant difference (p<0.001 and p<0.001, respectively).

Table I. Dosimetric comparison for PTVs between 3DCRT and CIRT, VMAT and CIRT.

| DVH parameters | Mean±SD | vs. 3DCRT | vs. VMAT |
|----------------|---------|-----------|----------|
| D98 [Gy, Gy(RBE)] | 40.1±0.4 | 40.9±1.4 | 41.0±0.4 | 0.002 | <0.001 |
| D95 [Gy, Gy(RBE)] | 40.9±0.3 | 41.7±1.0 | 41.4±0.4 | 0.007 | <0.001 |

OAR: Organ at risk; 3DCRT: three-dimensional conformal radiotherapy; VMAT: volumetric modulated arc therapy; CIRT: carbon-ion radiotherapy; RBE: relative biological effectiveness; DVH: dose-volume histogram; SD: standard deviation.
The D_{\text{max}} of the spinal cord was significantly lower in the CIRT plans than that of the 3D CRT and VMAT plans ($p<0.001$ and $p<0.001$, respectively). The D_{\text{max}} of the skin was significantly lower in the CIRT plans than that of the 3D CRT and VMAT plans ($p=0.001$ and $p<0.001$, respectively).

The DVH parameters for OARs according to the tumor site in CIRT are presented in Table III. For the heart, all parameters were significantly lower in the UT area. There was no significant difference between the MT and LT areas for DVH parameters of the heart. The Dmean of the heart was 1.3±1.6 Gy (RBE), 10.9±12 Gy (RBE), and 11.1±1.7 Gy (RBE) in the UT, MT, and LT areas, respectively. All the CIRT domestic variables in the LT area regarding the lung dose, except for the V_{50}, were significantly lower than those of the MT and UT areas. There was no significant difference between the UT and MT areas for DVH parameters of the lungs. The Dmean of the lungs was 1.9±0.6 Gy (RBE), 2.2±0.5 Gy (RBE), and 0.6±0.4 Gy (RBE) in the UT, MT, and LT areas, respectively. For both the spinal cord and the skin, the D_{\text{max}} was significantly higher in the UT area than that of the MT and LT areas.

**Discussion**

In the present study, we compared the radiation dose distribution of CIRT, 3D CRT, and VMAT for stage I esophageal cancer. The present study demonstrated that CIRT resulted in more optimal dose distribution to the target volume and a lower dose to OARs than 3D CRT and VMAT. To the best of our knowledge, this is the first report on the comparison of the radiation dose distribution between CIRT and XRT.

HI was lower in the CIRT plans in this study. A low HI means that there is little difference in the high irradiation area and low irradiation area within the target volume, demonstrating that a uniform dose was administered (22). In XRT, when the target volume was located close to the lungs, differences in the electron density can reduce the radiation dose in the target volume. Therefore, it can be difficult to maintain dose homogeneity in the target volume treated by XRT. However, it was suggested that even for such lesions of the chest, a uniform dose could be administered with CIRT.

In radiotherapy of esophageal cancer, it is essential to reduce toxicity in the heart and lungs because late cardiopulmonary toxicities can be life-threatening (2-4). It has been reported that the radiation dose to the heart was reduced by $^{\text{in vivo}}$35: 447-452 (2021)

OAR: Organ at risk; CIRT: carbon-ion radiotherapy; UT: upper thoracic; MT: midthoracic; LT: lower thoracic; RBE: relative biological effectiveness; DVH: dose-volume histogram; SD: standard deviation.
using IMRT (26). Because the particle beam with a Bragg peak can be reduced in organs that are deeper than the target, particle beam radiotherapy can further reduce the dose to normal organs. In fact, several studies have indicated that the radiation dose in the lungs and heart was reduced with PBT (15-17). Similar to these reports of PBT, the present study revealed that CIRT can provide significantly lower dose to the heart and lungs than XRT. CIRT reduced the mean radiation dose in the heart to <1/3 of 3DCRT and <1/2 of VMAT. The mean radiation dose to the lungs was also reduced to 1/3 of 3DCRT and 1/6 of VMAT. A comparison of the heart and lungs of the CIRT group with the VMAT group indicated that there was no significant difference in terms of V50. With VMAT, a radiation dose conforming to the target volume can be administered, and it was suggested that the volume of normal organ irradiated by the prescribed dose was small.

It has also been demonstrated that PBT can reduce the dose to the spinal cord as well (16). In the present study, a similar tendency was found; CIRT reduced the dose to the spinal cord to 50% of 3DCRT and 60% of VMAT. Spinal cord disorders result in a significant reduction in the quality of life. CIRT can be used to provide treatment with greater safety.

There have been no reports to date that compared the radiation dose in the skin. In the present study, CIRT demonstrated significant lower dose distribution to the skin than 3DCRT and VMAT. It has been found that the area irradiated with 40 Gy (RBE) of CIRT was a prognostic factor of acute dermatitis (20). Another study demonstrated that the area irradiated with 60 Gy (RBE) was a predictive factor of late skin toxicity (21). In the present study, the maximum dose of CIRT was sufficiently lower than that in these reports. It was suggested that there is little risk of severe adverse skin events.

A difference in radiation dose in OARs according to the tumor location has been reported. Shirai et al. have reported a high radiation dose in the heart with lesions of the distal esophagus (18). A dosimetric comparison study of PBT has also demonstrated that the mean dose of the heart has been affected by tumor site (15). In the present study, the radiation dose to the heart was significantly low in the MT and UT areas. Concerning the lungs, the radiation dose was significantly lower at LT esophagus compared with other sites. It was considered that the radiation dose to the lungs may have been relatively low because the heart was in the beam path. Whereas, the radiation dose in UT esophagus was significantly higher for the spinal cord and skin. In UT esophagus, it was considered that the spinal cord and skin were relatively close to the target volume compared with the other sites.

This study had several limitations. The subject sample size was small, appropriate irradiation field in CIRT remained unclear, and respiratory movement was not included. In actual treatment, respiratory movement is required to be evaluated using four-dimensional CT. Furthermore, our hospital is equipped with an in-room CT in the CIRT treatment room. The dose distribution robustness using the in-room CT should be evaluated.

In this study, favorable dose distribution was demonstrated with CIRT compared with XRT for esophageal cancer. It is expected that reducing the radiation dose to OARs will be useful for lowering the toxicity.
