(Received on September 27, 2017; accepted on November 21, 2017; originally published in Tetsu-to-Hagané, Vol. 102, 2016, No. 10, pp. 560–566)

In the continuous casting process of steels, the mold flux infiltrated in between a mold and solidified shell plays an important role to optimize lubrication and heat transfer to establish not only stable operation but also good surface quality of slabs. Therefore, lubrication and heat transfer was evaluated by measuring friction force attributed to the mold oscillation along with a lubrication model. The friction force was measured with a slab caster equipped with hydraulic oscillators, to understand how the friction force was affected by continuous casting factors such as the mold oscillation conditions, mold flux properties and casting speed.

It was found that the friction force was proportional to the velocity of the slab relative to the mold. The lubrication condition behaved as if it was fluid with the casting speed higher than 1.4 m/min.

In addition, the temperature dependence of viscosity of the molten flux was accounted for to develop a new fluid lubrication model. The present model showed that the lubrication layer thickness was approximately 50 μm.

Further, heat transfer through the mold flux was evaluated by the lubrication model revealing thermal resistance of the solidified flux layer, proving that the resistance caused by the crystallized flux was larger than that by glassy flux.

KEY WORDS: continuous casting; lubrication; friction force; heat transfer; mold flux; viscosity.

1. Introduction

In the continuous casting process of steels, the mold flux infiltrated in between a mold and solidified shell plays an important role to optimize lubrication and heat transfer to establish not only stable operation but also good surface quality of slabs. Mold flux is known as a key to stable continuous casting process because it controls primary cooling which affects the quality of initial solidified shell. A complex interaction of thermo-mechanical behaviors occurs between the mold and the solidified shell. Heat transfer, solidification, friction and lubrication determine not only the surface quality of the cast slabs, but also the productivity of the continuous casting process.

One of the essential requirements for higher casting productivity is high speed casting. However, high speed casting increases heat flux, by which longitudinal cracks may take place due to uneven solidification, especially for peritectic steels. The unevenness decreases with milder primary cooling in the mold applying a mold flux with a high solidification temperature.1–4 However, high solidification temperature flux leads to lower mold flux consumption rate causing higher mold friction, which increases the probability of slab surface cracking, mold sticking and even worse breakout. Therefore, it is necessary to clarify the behavior of the mold flux infiltrated in order to avoid slab surface cracking and mold sticking at higher casting speeds.

The thickness of the liquid flux between the solidified shell and the mold (lubrication layer) is able to be calculated by a mold flux consumption model,5 thermal analysis using the mold plate temperature6 and direct sampling from the mold after casting.7 These studies reported that the thickness of the lubrication layer was in the range from 50 to 200 μm. On the other hand, thickness of the lubrication layer can be estimated from the measured load during mold oscillation.8–15 Nakamori et al.8 and Omiya et al.9 have reported the thickness is not more than 20 μm. These values8,9 are smaller than the values estimated by the model analyses of the previous groups.5–7

In this study, lubrication and heat transfer was evaluated by measuring friction force attributed to the mold oscillation along with a lubrication model. The friction force was measured with a slab caster equipped with hydraulic oscillators, to understand how the friction force was affected by continuous casting factors such as the mold oscillation conditions, mold flux properties and casting speed.

2. Experiments

2.1. Measurement of Friction Force in a Mold

Figure 1 shows a schematic diagram of the steel and
mold flux components in the mold during the initial stage of the continuous casting process. The mold is in contact with the solidified shell through the lubrication layer of the liquid mold flux. Friction force is generated according to the flow direction with the magnitude of the velocity of the mold relative to the solidified shell. As reported by Nakamori et al.,\textsuperscript{8)} when the mold oscillation system is considered to be a mechanical vibration model, the equation of motion is shown as Eq. (1).

\[ M \ddot{x}_{MD} - C_D \dot{x}_{MD} - k x_{MD} - M g + F_f = 0 \]  \hspace{1cm} (1)

where, \( M \): mass of the mold (kg), \( x_{MD} \): displacement of the mold (mm), \( \dot{x}_{MD} \): velocity of the mold (m/min), \( \ddot{x}_{MD} \): acceleration of the mold, \( C_D \): damping constant (Ns/m), \( k \): spring constant (N/m), \( g \): acceleration of gravity (m/s\(^2\)), \( F_f \): forces applied to the solidified shell (N), \( F_{cy} \): force applied to the hydraulic cylinder (N).

Figure 2 shows a schematic diagram of the mold oscillating system, where the mold is oscillated by a hydraulic cylinder. The displacement of the mold was measured with an inductive sensor, while the pressure of the cylinder was measured with a hydraulic sensor. \( F_{cy} \) is expressed by Eq. (2).

\[ F_{cy} = \frac{L_1}{L_2} (P_R S_R - P_H S_H) \]  \hspace{1cm} (2)

where, \( L_1 \) and \( L_2 \): lengths from the pivot point (m), \( P_R \) and \( P_H \): rod side and head side pressures in the hydraulic cylinder (N/m\(^2\)), \( S_R \) and \( S_H \): areas of the rod side and head side surfaces on the piston head (m\(^2\)).

\( F_f \) can be obtained from Eqs. (1) and (2).

\[ F_f = -M \ddot{x}_{MD} - M g - C_D \dot{x}_{MD} - k x_{MD} + \frac{L_1}{L_2} (P_R S_R - P_H S_H) \]  \hspace{1cm} (3)

\( M, k \) and \( C_D \) can be determined off-line with the mold oscillation turned on. The condition was that the oscillation stroke was kept constant as 7 mm with the oscillation cycle changed from 50 to 200 count/min. In this case, the \( F_{MD} \) curve is identical to the \( F_{cy} \) curve since \( F_f = 0 \). Thereby, these constants were determined as \( M = 60 \ 500 \), \( k = 0 \), \( C_D = 400 \ 000 \) by the least squares method.

The difference between the maximum and the minimum values of the friction force \( F_f \), sum of tensile and compressive stresses loaded to the solidified shell, in one cycle was defined as the average friction force. The normalized friction force \( f_f \) is shown as Eq. (4).

\[ f_f = \frac{F_{f_{max}} - F_{f_{min}}}{2(W_{MD} + D_{MD}) L_{MD}} \]  \hspace{1cm} (4)

where, \( f_f \): normalized friction force (kPa), \( W_{MD} \): width of slab (m), \( D_{MD} \): thickness of slab (m), \( L_{MD} \): length of mold (m).

2.2. Casting Condition

The experimental conditions are listed in Tables 1 and 2. The carbon contents of the steels were in the range from 0.03 to 0.16 wt\%. The casting velocity was from 1.0 to 2.2 m/min. The slab sizes were 220/250 mm in thickness and 2 100 mm in width. Four types of mold fluxes with various viscosities and solidification temperatures were used to understand the effect of these properties. The oscillation stroke was chosen as 6, 7 or 9 mm with the cycle of 70 to 220 count/min. Negative strip time is defined as the duration with the velocity of the slab relative to the mold below zero, while the duration other than that positive strip time

| Table 1. Casting conditions. |
|-----------------------------|
| Steel grade (wt% C)         | 0.03–0.16  |
| Casting velocity (m/min)    | 1.0–2.2    |
| Slab size (mm)              | 220×2 100, 250×2 100 |
| Oscillation stroke (mm)     | 6, 7, 9    |
| Oscillation cycle (counts/min) | 70–220    |
3. Experimental Results

3.1. Effect of Casting Velocity on Friction Force

Figure 4 shows the relationship between the casting velocity and friction force. As the casting velocity increases, friction force also increases. The difference between the maximum and minimum values of the velocity of the solidified shell relative to the mold was defined as $\Delta V_c$. The mold oscillation cycle was controlled so that NSR (Negative Strip Ratio) became constant under all the casting conditions as shown in Fig. 3.

3.2. Effect of Properties of Mold Flux on Friction Force

Figure 5 shows the relationship between the friction force and the four types of mold fluxes. In Fig. 5(a), the oscillation stroke was kept constant as 6 mm, applying mold fluxes A and C with the casting velocity from 1.4 to 2.2 m/min. The friction force is proportional to the viscosity of the lubrication layer with the lubrication behaved as fluid. The friction force of flux C is higher than that of flux A in spite of the lower viscosity of flux C. This means that the friction force cannot be determined by the viscosity of the mold flux. Focusing on the solidification temperature, it is seen that the low viscosity flux is relatively high, which would contribute to the increase of the friction force. In Fig. 5(b), mold fluxes B and D with viscosities of 0.08 and 0.09 Pa·s respectively were used with the casting velocity from 1.4 to 2.2 m/min while holding the oscillation stroke constant as 7 mm. Compared with similar viscosity of flux B and D, the friction force was the largest with flux D, whose solidification temperature was the highest. Similarly to the case of the 6 mm stroke, this experiment also has revealed that higher solidification temperature results in higher friction force in the mold of continuous casting process.

3.3. Effect of Oscillation Stroke on Friction Force

Figure 6 shows the relationship between the friction force and properties of mold flux. The friction force cannot be determined by the viscosity of the mold flux as shown in Fig. 6(a). On the other hand, as the solidification temperature becomes higher, the friction force increases as shown in Fig. 6(b). The fact indicates that the solidification temperature would contribute to the increase in the friction force. In addition, the friction force is higher with the oscillation stroke of 6 mm than of 7 mm. This will be discussed next.
and the mold oscillation stroke applying mold flux C with the constant casting velocity of 1.8 m/min. Obviously, with increasing the oscillation stroke, the friction force decreases. It is known that mold flux consumption increases when the oscillation stroke is longer. In other words, the gap between the hook and the solidified flux is larger. Under this condition, a larger amount of the mold flux flows into the gaps to achieve more lubrication.

4. Discussion

4.1. Estimation of Temperature in Mold

In the case of liquid lubrication, the friction force is proportional not only to the mold flux viscosity but also to the relative velocity between the mold and the solidified shell. Meanwhile, it is inversely proportional to the thickness of the lubrication layer. However, in Fig. 5, the friction force with the lower viscosity flux is higher than that with the higher viscosity one. It should be noted that the values of viscosities at 1 300°C are employed as shown in Table 2. It is presumed that the temperature of the lubrication layer is different from 1 300°C. It is necessary to estimate the temperature of the lubrication layer, which can be estimated by a one-dimensional heat transfer calculation. Assuming that thickness of each layer in the mold is uniform, a schematic view of the temperature distribution in the mold can be drawn as Fig. 8. Assuming that no air gap exists between the mold and the solid flux layer, heat flux is expressed by Eq. (7).

\[
q = \frac{K}{d_t}(T_s - T_{cs}) \tag{7}
\]

where, 

- \( q \): heat flux (W/m²),
- \( T_{cs} \): temperature between solid and liquid flux (°C),
- \( T_s \): temperature between solidified shell and liquid flux (°C),
- \( K \): thermal conductivity of mold flux (W/mK).

Applying the temperature increase \( \Delta T \) of the mold cooling water, heat flux can be obtained by Eq. (8).

\[
q = C_w \Delta T q_w \tag{8}
\]

where,

- \( C_w \): specific heat of water (= 4.2 kJ/kg°C),
- \( q_w \): flow rate of mold cooling water (L/m²s).

Table 3 shows the conditions of the heat transfer calculation. \( T_{cs} \) can be approximated as the solidification temperature of the flux. Here, the thickness of the lubrication layer is once set to be 100 µm. The thermal conductivity \( K \) of 1.31 W/mK, has been reported by Yamauchi et al. The combination of Eqs. (7) and (8) along with the values in Table 3 shows that the temperatures on the solidified shell side of each flux range from 1 200 to 1 300°C proving that the average temperature in the lubrication layer is lower than 1 300°C.
4.2. Temperature Dependence of Mold Flux Viscosity

It is known that the viscosity of the mold flux increases as the temperature of the mold flux decreases. In order to estimate the viscosity of the lubricating layer, viscosity of each flux was measured by using a rotational viscometer in the temperature range from 1150 to 1300°C to have temperature dependence of viscosity. The Ar gas flow rate was set to be 2.5 L/min. Figure 9 shows the temperature dependence of the viscosity of each flux. At 1300°C, flux A has the highest viscosity. However, as the temperature decreases, the viscosities of the fluxes with the higher solidification temperatures increase sharply. One can understand that due to these phenomena, the friction forces with the higher solidification temperature fluxes are higher independently on the viscosity values at 1300°C, usually representing this property. This fact indeed implies that one has to take temperature dependence of viscosity into account.

4.3. Model of Lubrication in Mold

The temperature of the lubrication layer is calculated in order to establish a friction force model considering the temperature dependence of the flux viscosity as described above. It is known that the temperature dependence of the viscosity of glass melts is represented by Vogel-Tamman-Fulcher’s rule (VTF rule), which is shown in Eq. (9).

\[
\log \mu = C_0 + \frac{C_1}{T - T_{cs}} \quad \text{.............. (9)}
\]

where, \(C_0\) and \(C_1\): fitting parameters (–).

The temperature of the lubrication layer is defined by Fig. 8. Temperature distribution between molten steel and copper mold.

The combination of Eqs. (5), (9) and (11) gives the friction force expressed by Eq. (12) as a function of the lubrication layer thickness \(d_l\).

\[
F_i = \frac{V_c - V_{MD}}{d_l} \exp\left(\frac{C_0 + 2C_1K}{d_lq}\right) \quad \text{.............. (12)}
\]

The lubrication layer thickness can be calculated by using the measured friction force and mold heat flux. Figure 10 shows the casting velocity dependence of the lubrication layer thickness for each mold flux indicating that the lubricating layer ranges from about 40 to 50 μm. It can be seen that the thickness decreases as the casting velo-
ity increases, which is similar to the behavior reported by Nagano et al.\textsuperscript{6} Nakamori et al.\textsuperscript{8} and Omiya et al.\textsuperscript{9} have reported the thickness of the lubrication layer is not more than 20 μm based on the measurements of the friction force. Hanao et al.\textsuperscript{7} has reported that the thickness of the lubrication layer estimated by direct sampling from the upper part of the mold is from 50 to 200 μm. It is postulated that the results of this study estimated from the averaged friction force in the mold also give the thickness of the lubrication layer averaged as for the casting direction. Therefore, the averaged lubrication layer thickness may be underestimated focusing on the upper part of the mold corresponding to the positions beneath the meniscus. However, the thickness of 40 to 50 μm are closer to the directly measured values\textsuperscript{7} than the values previously estimated from the friction force.\textsuperscript{8,9} This indicates that it is quite necessary to consider the temperature dependence of the viscosity of the mold flux to create the lubrication model.

4.4. Estimation of Heat Transfer in Mold

Figure 11 shows the relationship between the thickness of the lubrication layer and the heat flux in the mold. The heat flux in the mold was calculated from the temperature difference of the mold cooling water (Eq. (8)). It can be seen that as the lubrication layer thickness decreases, the heat flux increases. One reason for this increase is the decrease in thermal resistance of the lubrication layer. On the other hand, the lubrication layer tends to be thinner with increasing the casting velocity, as shown in Fig. 10. Therefore, another reason for the increase of heat flux is the increased throughput due to higher casting velocity.

Compared at the same lubrication layer thickness, fluxes B, C and D, which have the higher solidification temperatures obviously show the lower heat fluxes than flux A with the higher viscosity. In general, the heat flux through the mold flux film is influenced by conditions such as heat conduction, radiation and the air gap between the lubrication layer and the solid flux layer. In addition, the thermal conductivity of the mold flux does not vary so much within the actual range of the flux compositions.\textsuperscript{22} It is considered that the thermal resistances of the lubrication layer exhibit the values similar to each other in all the fluxes tested in this study under the condition of the same lubrication layer thickness. The present result has proven that, in an actual continuous casting machine, mild cooling condition can be accomplished with the flux with higher solidification temperature that brings the higher thermal resistance of the solid flux layer.

5. Conclusions

Lubrication and heat transfer was evaluated by measuring friction force attributed to the mold oscillation along with a lubrication model. The friction force was measured with a slab caster equipped with hydraulic oscillators, to understand how the friction force was affected by continuous casting factors such as the mold oscillation conditions, mold flux properties and casting speed. The main results are summarized as follows.

(1) The friction force was proportional to the velocity of the slab relative to the mold. The lubrication condition behaved as if it was fluid with the casting speed higher than 1.4 m/min.

(2) Higher solidification temperature of mold flux results in higher friction force in the mold. This was considered to be due to an increase of viscosity near the solidification temperature.

(3) The temperature dependence of viscosity of the molten flux was accounted for to develop a new fluid lubrication model. The present model showed that the lubrication layer thickness was approximately 50 μm.

(4) Heat transfer through the mold flux was evaluated by the lubrication model revealing thermal resistance of the solidified flux layer, providing that the resistance caused by the crystallized flux was larger than that by glassy flux.
