(August 9, 1999)

With decreasing particle size, different mechanisms dominate the thermally activated magnetization reversal in ferromagnetic particles. We investigate some of these mechanisms for the case of elongated, single-domain nanoparticles which we describe by a classical Heisenberg spin chain driven by an external magnetic field. For sufficiently small system size the magnetic moments rotate coherently. With increasing size a crossover to a reversal due to soliton-antisoliton nucleation sets in. For even larger systems many of these soliton-antisoliton pairs nucleate at the same time. These effects give rise to a complex size dependence of the energy barriers and characteristic time scales of the relaxation. We study these quantities using Monte Carlo simulations as well as a direct integration of the Landau-Lifshitz-Gilbert equation of motion with Langevin dynamics and we compare our results with asymptotic solutions for the escape rate following from the Fokker-Planck equation. Also, we investigate the crossover from coherent rotation to soliton-antisoliton nucleation and multi-droplet nucleation, especially its dependence on the system size, the external field and the anisotropy of the system.

I. INTRODUCTION

Many novel physical effects occur in connection with the decreasing size of the systems which are under investigation. Magnetic materials are now controllable in the nanometer regime and there is a broad interest in the understanding of the magnetism of small magnetic structures and particles due to the broad variety of industrial applications. Magnetic particles which are small enough to be single-domain are proposed to have good qualities for magnetic recording and arrays of isolated, nanometer-sized particles are thought to enhance the density of magnetic storage. But on the other hand there is an ultimate limit for the density of magnetic storage which is given by that size of the particles below which superparamagnetism sets in. Therefore, the role of thermal activation for the stability of the magnetization in nanometer-sized structures and particles is studied at present experimentally as well as theoretically.

Wernsdorfer et al. measured the switching times in isolated nanometer-sized particles and wires. For small enough particles they found agreement with the theory of Néel and Brown who described the magnetization switching in Stoner-Wohlfarth particles by thermal activation over a single energy barrier following from coherent rotation of the magnetic moments of the particle. For larger particles and also for wires nucleation processes and domain wall motion were found to become relevant.

Asymptotic formulae for the escape rates following from corresponding Fokker-Planck equations have been derived for ensembles of isolated Stoner-Wohlfarth particles as well as for a one-dimensional model.

Most of the numerical studies of the magnetization switching base on Monte Carlo methods. Here, mainly nucleation phenomena in Ising models have been studied but also vector spin models have been used to investigate the magnetization reversal in systems with many, continuous degrees of freedom qualitatively. However, Monte Carlo methods - even though well established in the context of equilibrium thermodynamics - do not allow for a quantitative interpretation of the results in terms of a realistic dynamics. Only recently, a Monte Carlo method with a quantified time step was introduced. Here, the interpretation of a Monte Carlo step as a realistic time interval was achieved by a comparison of one step of the Monte Carlo process with a time interval of a Langevin equation, i.e., a stochastic Landau-Lifshitz–Gilbert equation.

Numerical methods for the direct integration of a Langevin equation are more time consuming than a Monte Carlo method but nevertheless highly desirable since here, naturally, a realistic time is introduced by the equation of motion. The validity of different integration schemes is still under discussion (see for a discussion of the validity of Itô and Stratonovich integration schemes) and, hence, here, as well as for the Monte Carlo methods, the investigation of analytically solvable models as test tools for the evaluation of the numerical techniques are desirable.

In this paper we will consider a chain of classical magnetic moments — a system which can be interpreted as a simplified model for ferromagnetic nanowires or extremely elongated nanoparticles. This model is very useful for two reasons: i) since it was treated analytically asymptotic results for the energy barriers as well as for the escape rates are available. Hence, the model can be used as a test tool for numerical techniques. ii) Depending on the system size, given anisotropies and the strength of the magnetic field different reversal mechanisms may appear and can be investigated. For small sys-
tem sizes the magnetic moments are expected to rotate coherently [3], while for sufficiently large system sizes the so-called soliton-antisoliton nucleation is proposed [3]. Therefore, a systematic numerical investigation of the relevant energy barriers, time scales, and of the crossover from coherent rotation to nucleation is possible.

The outline of the paper is as follows. In Sec. II first we introduce the model and we compare the two different numerical techniques mentioned above, namely the Monte Carlo method and the numerical solution of the Langevin equation, both of which we will use throughout the paper. In Sec. III we compare our numerical results with the theoretical considerations of Braun, concerning the energy barriers as well as the mean first passage times for magnetization switching by coherent rotation as well as by soliton-antisoliton nucleation. For higher temperatures or driving fields, we also find a crossover to multidroplet nucleation, similar to what is known from Ising models. In section IV we summarize our results and relate them to experimental work.

II. MODEL AND METHODS

A. Model

Our intention is to compare our numerical results with Braun’s analytical work which bases on a continuum model for a magnetic nanowire. For our numerical investigations we use a discretized version of this model namely a one dimensional classical Heisenberg model. We consider a chain of magnetic moments of length $L$ (number of spins) with periodical boundary conditions defined by the Hamiltonian,

$$
E = -J \sum_{(ij)} \mathbf{S}_i \cdot \mathbf{S}_j - d_x \sum_i (S_i^x)^2 \\
+ d_z \sum_i (S_i^z)^2 - \mu_s B \cdot \sum_i \mathbf{S}_i. \tag{1}
$$

where the $\mathbf{S}_i = \mu_i/\mu_s$ are three dimensional magnetic moments of unit length. The first sum which represents the exchange of the magnetic moments is over nearest neighbor interactions with the exchange coupling constant $J$. The second and third sum represent uniaxial anisotropies of the system where the $x$-axis is the easy axis and the $z$-axis the hard axis of the system (anisotropy constants $d_x = 0.1J$, $d_z = J$). These anisotropy terms may contain contributions from shape anisotropy as well as crystalline anisotropies [3]. Even though an exact treatment of dipolar interactions would be desirable we let this problem for future work so that our results presented here are comparable to the analytical work of Braun. The last sum is the coupling of the moments to an external magnetic field, where $\mathbf{B}$ is the induction.

All our simulations using the two different methods above start with a configuration where all magnetic moments point into the $x$ direction, antiparallel to the external magnetic field $\mathbf{B} = -B_y \hat{x}$.

The time $\tau$ when the $x$-component of the magnetization changes its sign averaged over many simulation runs (100-1000, depending on system size and simulation method) is the most important quantity which we determine. In the case where the temperatures is low compared to the energy barrier the system is in the metastable initial state for a very long time while the time needed for the magnetization reversal itself is extremely short. In this case $\tau$ can be considered to be the so-called mean first passage time required to overcome the energy barrier. For low enough temperatures the mean first passage time should also be comparable to the reciprocal of the escape rate $\lambda$ which has been calculated for the model considered here asymptotically from the Fokker-Planck equation in certain limits (for details see [4]). In the classical nucleation theory the so-called lifetime or nucleation time is the time required by the system to build a supercritical droplet which from then on will grow systematically and reverse the system. The metastable lifetime was measured numerically in Ising models by use of similar methods [10, 21]. For low enough temperature $T$ all the different times mentioned above are expected to coincide.

B. Langevin dynamics

The equation describing the dynamics of a system of magnetic moments is the Landau-Lifshitz-Gilbert (LLG) equation of motion with Langevin dynamics. This equation has the form

$$
\frac{(1+\alpha^2)\mu_s}{\gamma} \frac{\partial \mathbf{S}_i}{\partial t} = \mathbf{S}_i \times \left( \zeta_i(t) - \frac{\partial E}{\partial \mathbf{S}_i} \right) \\
- \alpha \mathbf{S}_i \times \left( \mathbf{S}_i \times (\zeta_i(t) - \frac{\partial E}{\partial \mathbf{S}_i}) \right), \tag{2}
$$

with the gyromagnetic ratio $\gamma = 1.76 \times 10^{11}(\text{Ts})^{-1}$, the dimensionless damping constant $\alpha$. The first part of Eq. 2 describes the spin precession while the second part includes the relaxation of the moments. In both parts of this equation the thermal noise $\zeta_i(t)$ is included representing thermal fluctuations, with $\langle \zeta_i(t) \rangle = 0$ and $\langle \zeta_i^+(t)\zeta_j^-(t') \rangle = 2\delta_{ij}\delta(t-t')2\alpha k_B T \mu_s / \gamma$ where $i,j$ denote the lattice sites and $k,l$ the cartesian components. Eq. 2 is solved numerically using the Heun method which corresponds to the Stratonovich discretization scheme [20]. Note, that since the Langevin dynamics simulations are much more time consuming than the Monte Carlo simulation we use this method here mainly for comparison and we will present only data for the relaxation on shorter time scales.

2
C. Monte Carlo simulations

It is inconceivable that the Langevin dynamics simulation can be used over the whole time scale of physical interest so that we simulate the system also using Monte Carlo methods [27] with a heat-bath algorithm. Monte Carlo approaches in general have no physical time associated with each step, so that an unquantified dynamic behavior is represented. However, we use a new time quantified Monte Carlo method which was proposed in [24] where the interpretation of a Monte Carlo step as a realistic time interval was achieved by a comparison of one step of the Monte Carlo process with a time interval of the LLG equation in the high damping limit. We will use this algorithm in the following. The trial step of this algorithm is a random movement of a magnetic moment within a cone of size $r$ with

$$r^2 = 20k_B T \alpha \gamma(1 + \alpha^2) \mu_s \Delta t.$$ (3)

Using this algorithm one Monte Carlo step represents a given time interval $\Delta t$ of the LLG equation in the high damping limit as long as $\Delta t$ is chosen appropriately (for details see [24]).

![Theoretical and numerical results for the first passage time $\tau_{\gamma}/\mu_s$ vs. damping constant $\alpha$. The data are from Monte Carlo and Langevin dynamics simulations for $k_B T = 0.025J$ and $L = 80$. Solid lines are guides to the eye.](image)

To test the algorithm, in Fig. 1 the $\alpha$ dependence of the mean first passage time of the Monte Carlo data is compared with the data of the Langevin dynamics simulation. Each data point is an average over 1000 independent runs. For low values of the damping constant the data do not coincide while in the high damping limit Monte Carlo and Langevin dynamics data converge. Hence, throughout this work we will use $\alpha = 4$, which is large enough so that our Monte Carlo simulation and the numerical solution of Eq. 2 yield identical time scales. Even though this is an unphysically large value for $\alpha$ we can compare our results with the analytically obtained high damping asymptotes.

III. RESULTS

We investigate the influence of the system size on the occurring reversal mechanisms. There are two extreme cases of reversal mechanisms which might occur in our model namely coherent (or uniform) rotation and nucleation. For small system sizes all magnetic moments of the particle rotate uniformly in order to minimize the exchange energy. For larger system sizes it is favorable for the system to divide into parts of opposite directions of magnetization parallel to the easy axis which minimizes the anisotropy energy. This is a magnetization reversal driven by nucleation and subsequent domain wall propagation. The crossover between these mechanisms is discussed later in this section. First, we study the different reversal mechanism and compare our numerical data with theoretical formulae.

A. Coherent Rotation

In the case of small chain length the magnetic moments rotate coherently while overcoming the energy barrier which is due to the anisotropy of the system. The first theoretical description of the coherent rotation of elongated single-domain particles was developed by Stoner and Wohlfarth [28]. The belonging energy barrier is

$$\Delta E_{cr} = L d_s (1 - h)^2$$ (4)

with $h = \mu_s B_z/(2d_s)$. Néel expanded this model for the case of thermal activation [6] and Brown [8] calculated the escape time

$$\tau = \tau_{cr}^* \exp \frac{\Delta E_{cr}}{k_B T}$$ (5)

following a thermal activation law. The prefactor $\tau^*$ is not a simple constant attempt frequency as claimed frequently by several authors but a complicated function which in general may depend on system size, temperature, field and anisotropies. For our model it is

$$\tau_{cr}^* \gamma = \frac{\pi(1 + \alpha^2)}{\alpha(1 - h^2) - \alpha(1 - h^2) + \sqrt{\alpha(1 - h^2) + \alpha d_s (1 - h^2)^2 + 4d_s d_s (1 - h^2)}}$$ (6)

as was calculated from the Fokker-Planck equation [10].

The main assumption underlying all results above is that the system can be described by a single degree of freedom, namely the magnetic moment of the particle which must have a constant absolute value. Then, the equations above should hold for low enough temperatures $k_B T \ll \Delta E_{cr}$ and for $\mu_s B_z < 2d_s$. For larger fields the energy barrier is zero, so that the reversal is spontaneous without thermal activation (non-thermal magnetization reversal).

In the following, our numerical results for the mean first passage times $\tau$ for coherent rotation are compared
with the equations above. Fig. 2 shows the temperature dependence of \( \tau \) for a given value of the external magnetic field \( h = 0.75 \) and three different system sizes. For temperatures \( k_B T < \Delta E_{cr} \) our data confirm the asymptotic solutions above for smaller system sizes.

For the largest system shown here (\( L = 16 \)) the numerical data are systematically lower than the theoretical prediction. Obviously, the prefactor \( \tau_{\text{cr}}^* \) depends on the system size in contradiction to Eq. 3 while the energy barrier (Eq. 2) is obviously still correct (the slope of the data). This size dependence of \( \tau_{\text{cr}}^* \) can be explained with the temperature dependence of the absolute value of the magnetic moment of the extended system. In an extended system, the energy barrier for vanishing field, \( d_x L \), is reduced to \( d_x \sum_i (S_i^x)^2 \) which expanded to first order of the temperature can lead to corrections of the form \( d_x \sum_i (S_i^x)^2 \approx d_x L (1 - a T) \). Including this in Eq. 3 remarkably leads to an effective reduction of the prefactor \( \tau_{\text{cr}}^* \) by a factor \( \exp(-a d_x L) \) and not to a reduction of the effective energy barrier \( \Delta E_{cr} \). To conclude, in extended systems with many degrees of freedom the reduction of the magnetization leads effectively to a size dependent reduction of the prefactor of the thermal activation law for low temperatures.

**B. Soliton-Antisoliton Nucleation**

With increasing length of the chain a different reversal mechanism becomes energetically favorable, namely the so-called soliton-antisoliton nucleation proposed by Braun [14]. Here, during the reversal the system splits into two parts with opposite directions of magnetization parallel to the easy axis. These two parts are separated by two domain walls with opposite directions of rotation in the easy \( x - y \)-plane (a soliton-antisoliton pair) which pass the system during the reversal.

Note, that we consider periodic boundary conditions, otherwise also the nucleation of one single soliton at one end of the chain would be possible. The energy barrier \( \Delta E_{nu} \) which has to be overcome during this nucleation process is [4]

\[
\Delta E_{nu} = \sqrt{2J d_x (4 \tanh R - 4hR)},
\]

with \( R = \text{arcosh}(\sqrt{1/h}) \). In the limit of small magnetic fields, \( h \to 0 \), this energy barrier has the form \( \Delta E_{nu} = 4 \sqrt{2J d_x} \) which represents the well-known energy of two domain walls. The corresponding mean first passage time follows once again a thermal activation law (see Eq. 5). Since our Monte Carlo simulations are for rather large damping, \( \alpha = 4 \), we compare our numerical data with the prefactor obtained in the over-damped limit (Eq. 5.4 in [14]) which in our units is

\[
\frac{\tau_{\text{nu}}^* \gamma}{\mu_s} = \frac{\pi^{3/2} (1 + \alpha^2) (k_B T)^{3/2} (2J)^{1/4}}{16 \alpha L d_x^{3/4} E_0(R) \tanh R^{3/2} \sinh R}
\]

The eigenvalue \( E_0(R) \) has been calculated numerically in [14]. In the limit \( h \to 1 \) it is \( E_0(R) \approx 3 R^2 \). The \( 1/L \) dependence of the prefactor reflects the size dependence of the probability of nucleation. The larger the system the more probable is the nucleation process. Furthermore, the prefactor has a remarkable \( \sqrt{T} \) dependence leading to a slight curvature in the semi-logarithmic plot of the thermal activation law (see Eq. 5).

Fig. 3 shows the temperature dependence of the reduced mean first passage time for \( h = 0.75 \) and two different system sizes. The data are from Monte Carlo (open symbols) and Langevin dynamics (filled symbols) simulations. The solid lines are the asymptotic formulae for the inverse escape rates for a single soliton-antisoliton nucleation process (see Eqs. 3, 5, and 6) and multiple nucleation (see Eq. 7).
dynamics and Monte Carlo simulations deviate from the formulae above. Interestingly, in this region the mean first passage times do not depend on system size in contrast to Eq. 8 where a $1/L$-dependence occurs due to the size dependence of the nucleation probability.

\[
\tau_{\text{mn}} = \left( \frac{L}{2v} \right)^{1/2} \frac{(D+1)\tau_{\text{nu}}}{v} \exp \frac{\Delta E_{\text{nu}}}{(D+1)k_B T}. \tag{10}
\]

For the one dimensional system which we consider in this paper the lifetime is given by

\[
\tau_{\text{mn}} = \sqrt{\frac{L\tau^*_{\text{nu}}}{v}} \exp \frac{\Delta E_{\text{nu}}}{2k_B T}. \tag{11}
\]

This means that the (effective) energy barrier for the multidroplet nucleation is reduced by a factor 1/2 and the prefactor $\tau^*_{\text{nu}}$ does no longer depend of the system size since $\tau^*_{\text{nu}}$ for the soliton-antisoliton nucleation has a $1/L$-dependence (see Eq. 5). Since we do not know the value of the domain wall velocity we had to fit this parameter which influences the prefactor $\tau_{\text{mn}}$ for the comparison in Fig. 3 in the intermediate temperature range. Nevertheless, in Fig. 3 the reduction of the slope of the curve by the factor 1/2 in the multidroplet regime is confirmed. Also, it can be seen, that the prefactor is not dependent on the system size since the data for both sizes coincide as is explained by the considerations above (we used the same value for $v$ of course for both curves, since $v$ should not depend on the system size).

A similar crossover from single to multidroplet excitations was observed in Ising models, field dependent \[17\] \[29\] as well as temperature dependent \[21\]. Comparing the mean first passage times for single and multidroplet nucleation we get for the intersection of these two times the crossover condition

\[
L_{\text{sm}} = \sqrt{v\tau^*_{\text{nu}}L_{\text{sm}}} \exp \frac{\Delta E_{\text{nu}}}{2k_B T}. \tag{12}
\]

The corresponding time is $L_{\text{sm}}/v$ — the time that a domain wall needs to cross the system. This results is also comparable to calculations in Ising models \[21\].

C. Multidroplet Nucleation

The mean first passage time $\tau_{\text{mn}}$ for the multidroplet nucleation can be calculated with the aid of the classical nucleation theory \[29\] \[30\]. In the case of multiple nucleation many nuclei with a critical size originate within the same time. These supercritical nuclei grow and join each other leading to the magnetization reversal. The mean first passage time for this process is determined by the probability for the occurrence of supercritical nuclei $1/\tau_{\text{nu}}$ and the time that is needed for the growth of the nuclei. Let us assume that the radius of a supercritical nucleus grows linearly with the time $t$. Then $\tau_{\text{mn}}$ is given by the condition that the change of the magnetization $\Delta M$ equals the system size \[19\],

\[
\Delta M(\tau_{\text{mn}}) = \int_0^{\tau_{\text{mn}}} \frac{(2vt)^D}{\tau_{\text{nu}}} \, dt = L^D, \tag{9}
\]

where $v$ is the domain wall velocity and $D$ the dimension of the system. Hence, the time when half of the system is reversed is given by

\[
\tau_{\text{mn}} = \left( \frac{L}{2v} \right)^{1/2} \frac{(D+1)\tau_{\text{nu}}}{v} \exp \frac{\Delta E_{\text{nu}}}{(D+1)k_B T}. \tag{10}
\]

In this section we are interested in the crossover between coherent rotation and soliton-antisoliton nucleation. Therefore, we compare the energy barrier of soliton-antisoliton nucleation (see Eq. 1) with the energy barrier of coherent rotation (see Eq. 4) in order to obtain a condition for the mechanism with the lowest activation energy. The resulting crossover line $L_c$ has the form

\[
L_c = \frac{\sqrt{2Jd_x(4\tanh R - 4hR)}}{d_x(1-h)^2}. \tag{13}
\]

For vanishing magnetic field it is $L_c = 4\sqrt{2J/d_x}$ and we get the simple condition that four domain walls (not two!)
have to fit into the system. Note, that Braun also determined this crossover line \[ L_{\text{sm}} \] from a slightly different condition. He calculated the system size below which no nonuniform solution for the Euler-Lagrange equations exists and he obtained a limit which is similar to Eq. 13 but a little bit lower.

A diagram showing which reversal mechanisms occur in our model depending on system size and field is presented in Fig. 5. The crossover line \( L_{c} \) derived above separates the coherent rotation region from that of soliton-antisoliton nucleation. For \( h > 1 \) the reversal is nonthermal. In the nucleation region, for larger fields a temperature dependent crossover to multiple nucleation sets in. However, the lower the temperature the more vanishes this region. As an example we show in the figure the line \( L_{\text{sm}} \) which separates single from multiple nucleation for \( k_{B}T = 0.006J \) and under the assumptions that the domain wall velocity is proportional to the field \[ h \].

![Fig. 5](image1)

**FIG. 5.** The diagram shows the regions of different reversal mechanisms. The lines correspond to Eq. [3] and [4]. The points are data from Monte Carlo simulations confirming Eq. [13].

In order to confirm Eq. [3] numerically we determine the mean correlations of the \( y \)-components of two spins located in a distance of \( L/2 \) (the maximum distance in a system with periodic boundary conditions) at the time \( \tau \) during the reversal

\[
c_{y}(L/2) = \left[ \frac{1}{N} \sum_{i=1}^{N} S_{y}^{i}(\tau)S_{y}^{i+L/2}(\tau) \right]_{av}.
\]

This quantity characterizes the reversal mechanism. Fig. 5 shows the system size dependence of \( c_{y}(L/2) \) for different values of the magnetic field. For coherent rotation the limiting value of \( c_{y}(L/2) \) is 1 since at the time \( \tau \) all moments point into the \( y \)-direction (small systems). On the other hand, for nucleation the system is mainly split into two parts where the moments point into \( \pm x \)-direction. In this case the correlations in \( y \)-direction are zero (larger system size). As a criterion for the crossover between nucleation and coherent rotation we use a value of 1/2 for the correlation function and define the corresponding system size as the crossover length. This analysis leads to the numerical data shown in Fig. 5.

![Fig. 6](image2)

**FIG. 6.** System size dependence of \( c_{y}(L/2) \) for different magnetic fields. \( k_{B}T = 0.1 \ldots 0.004J \) depending on \( h \).

The MC data confirm the theoretical crossover line except for the largest magnetic field. Here, the numerical data differ from the theoretical crossover line which diverges in the limit \( h \to 1 \). In this region a mixed reversal mechanism appears: first the magnetic moments rotate coherently up to a certain rotation angle and then an instability sets in and a (restricted) soliton-antisoliton pair arises. Obviously, the coherent rotation is unstable in this region. A hint for the existence of this mixed mechanism can also be found in Fig. 6 for the field \( h = 0.95 \) the correlation is not zero for large system sizes but remains finite due to the fact that the whole system first rotates by a certain angle before the nucleation sets in.

**IV. CONCLUSIONS**

We investigated the magnetization switching in a classical Heisenberg spin chain which we consider as simple model for nanowires or elongated nanoparticles and as a test tool for numerical techniques since analytical expressions for the relevant energy barriers and time scales exist in several limits. Numerically we used Monte Carlo methods as well as Langevin dynamics simulations and we confirmed that the Monte Carlo algorithm we use yield time quantified data comparable to those of the Langevin dynamics simulation in the limit of high damping.

Varying the system size we observed different reversal mechanisms, calculated the mean first passage times for the reversal (i.e. the time scale of the relaxation process) and compared our results with analytical considerations. The comparison of our numerical data with theoretical considerations confirms that both of our numerical techniques can be used to study the relaxation behavior of magnetic systems qualitatively and quantitatively.
tem size

depend on the system size but the prefactor (Eq. 8) has a

antisoliton nucleation the energy barrier (Eq. 7) does not

netization of extended systems. In the regime of soliton-

h

tivation (Eq. 5) in the three regimes explained above for

ercivity. Solving the equation describing the thermal ac-

found in the particle size dependence of the dynamic co-

sage time remains constant (Eq. 11).

here on with increasing system size the mean first pas-

crossword from coherent rotation to nucleation occurs (see Eq. 13). This decrease ends where the so-

crossover length should be of

J

The solid lines are the appropriate formulae

for CoPt particles the crossover length should be of

the order of 30nm which is also roughly in agreement

with experiments on Co particles.

We should mention that the model treated here con-

ains magnetostatic energy only in a local approxima-

tion. Arguments against this treatment have been

brought forward so that the question wether an ex-

plicit inclusion of the dipole-dipole interaction would lead

to additional reversal modes (e. g. curling) - also depend-

ing on wether the diameter of the nanowire is larger or

smaller than the exchange length - remains open. Calcula-

tions following these lines are therefore highly desirable.
