Abstract
The effect of spinning rates on mechanical properties and hydrogen absorption/desorption properties of Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ amorphous ribbons have been investigated in the present work. A fully amorphous structure was confirmed by x-ray diffraction (XRD) and transmission electron microscopy (TEM) analysis of the ribbons obtained from spinning rates of 30 m s$^{-1}$ to 45 m s$^{-1}$. The uniformity of amorphous ribbons and their mechanical properties were improved with the increase in the spinning rate. Scanning electron microscopy (SEM) revealed that the fracture surface of amorphous ribbons had a cleavage feature and vein-like pattern when the spinning rates were 30 m s$^{-1}$ and 45 m s$^{-1}$, respectively. Because of the influence of flow units on the kinetic process of hydrogen absorption, the hydrogenation kinetics and hydrogen desorption capacity of amorphous ribbons were enhanced with the increased spinning rates. After the amorphous ribbons absorbed a large amount of hydrogen, ZrH$_2$, TiH$_2$, and (ZrTi)$_2$Ni$_7$ crystalline phases were formed from the amorphous matrix. Hydrogen promotes amorphous phase decomposition and the crystallinity of the new phases led to deterioration of the mechanical properties.

Keywords Amorphous ribbons · mechanical properties · hydrogen absorption properties · spinning rate

Introduction
Amorphous alloys have attracted much attention due to their excellent corrosion resistance and hydrogen absorption properties, especially mechanical properties such as outstanding mechanical strength, greater elasticity than crystalline alloys, high hardness, and good fatigue resistance. Amorphous alloys refer to alloys in which atoms are arranged in a topological disorder in three-dimensional space and are relatively stable in a certain temperature range. There are no defects such as vacancies, grain boundaries, and stacking faults in amorphous alloys; this special structure gives amorphous alloys different mechanical properties and fracture mechanisms as compared to crystal alloys. The research on the mechanical properties of amorphous alloys is mainly a study of the mechanical properties of bulk amorphous and amorphous composite ribbons. There are few studies on melt-spun amorphous ribbons obtained by melt-spinning method because of their brittleness and fracture toughness. Therefore, some studies have been done to improve the ductility and toughness of amorphous ribbons, including changing the chemical composition of alloy, the melt-spinning rate, and heat-treatment process.

Due to the long-range disorder structure of amorphous alloys, there are areas where the atomic arrangement is loose or the interatomic bond is weak, which provides a channel for the diffusion and occupancy of hydrogen; these mechanisms have led to extensive research. Ti-based and Zr-based amorphous alloys have a strong affinity for H atoms, and they have been extensively studied. The hydrogen absorption characteristics of amorphous alloys are as follows: First, hydrogen preferentially occupies a lower-energy level in amorphous alloys and forms an amorphous solid/solution phase. Second, relative to crystalline alloys, amorphous alloys have a low activation temperature and hydrogen absorption temperature. Therefore, amorphous ribbons have broad application prospects in the purification of hydrogen, hydrogen storage alloys, and hydrogen permeation membranes.
In the present work, the effects of the spinning rate on the phase structure and mechanical properties were investigated, as well as the effects on the hydrogen absorption/desorption properties. The results revealed the relationship between mechanical properties and fracture mechanism at room temperature, and also explain the evolution of phase in hydrogen absorption.

**Materials and Methods**

Ingots with stoichiometric composition Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ were prepared by arc melting the mixture of pure metals Ti (99.99%), Zr (99.99%), Ni (99.99%), and Cr (99.99%) in an argon atmosphere. The ingots were re-melted four times for homogenization. Ribbons were obtained by melt spinning on a copper roller in an argon atmosphere, and the melt-spinning rates were 15 m s$^{-1}$, 30 m s$^{-1}$, 35 m s$^{-1}$, 40 m s$^{-1}$, and 45 m s$^{-1}$. During the melt-spinning process, the distance between the orifice of a quartz crucible and a copper wheel surface was maintained at 7.5 mm. The chamber pressure was maintained at 0.05 MPa.

The phase structure was characterized by a D/Max-2200 x-ray diffractometer (Rigaku Corporation, Akishima-Shi, Tokyo, Japan) using Cu Kα radiation. The thermal behaviors were analyzed by differential scanning calorimetry (DSC, PE DIAMOND) at a heating rate of 20 K min$^{-1}$ under an argon atmosphere. The microstructure and chemical composition were investigated using a JSM-6700F scanning electron microscope with an energy-dispersive spectrometer, and a JEM-2010F transmission electron microscope equipped with energy dispersive x-ray spectroscopy (EDX) functionality. The samples were prepared with a circle of 2 mm in diameter and then thinned using a double-jet electrolytic thinning device (MTP-1A) with 20% perchloric acid and 80% acetic acid. The mechanical properties, such as tensile strength ($\sigma_b$), elongation ($\delta$), and elastic modulus ($E$), were measured with a Zwick electronic universal testing machine operating at a loading rate of 8.3 × 10$^{-6}$ m s$^{-1}$ at room temperature. The hydrogen absorption/desorption properties were carried out in a fully automated hydrogen storage setup (fully automatic PCI monitor produced by Suzuki Shokan Co., Ltd.) at room temperature under hydrogen pressure of 3 MPa. The activation procedure involved heating the sample in vacuum for 2 h at 473 K.

**Results and Discussion**

Figure 1a presents the evolution of the x-ray diffraction (XRD) patterns of Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ alloy ribbons with spinning rates increasing from 15 m s$^{-1}$ to 45 m s$^{-1}$. The XRD patterns show different phase structures with different spinning rates. When the spinning rate was 15 m s$^{-1}$, the XRD patterns in the Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ alloy confirmed mainly the presence of α-Ti (PDF# 65-3362), α-Zr (PDF# 89-4892), and Ti$_2$Ni (PDF# 18-0898). However, with the spinning rate ranging from 30 m s$^{-1}$ to 45 m s$^{-1}$, the XRD patterns of ribbons exhibited only a broad diffraction peak. These results indicated that the Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ alloy ribbons presented a disordered structure in terms of atomic arrangement and consisted of a single amorphous phase when melt-spun at high speed. It was also revealed that the phase structure changed from crystalline to amorphous when the spinning rate increased from 15 m s$^{-1}$ to 45 m s$^{-1}$.

For DSC analysis of the amorphous ribbons, we selected representative melt-spun samples when the spinning rate was 30 m s$^{-1}$ and 45 m s$^{-1}$. The results of DSC curves are shown in Fig. 1b. The measurement results indicate that the DSC curves had an exothermic peak. It can be seen from the DSC curve that when the spinning rate was 30 m s$^{-1}$ and 45 m s$^{-1}$, the glass transition temperature was 785 K and 820 K, respectively. It was also indicated that when the spinning rate reached 30 m s$^{-1}$, the ribbons contained an amorphous phase. Thus, the glass transition temperature and glass transition behavior were related to the spinning rate. It was indicated that as the spinning rate increased, the thermal stability of the amorphous ribbon was strengthened. This is also consistent with published results on Ti-Zr-Ni-Cr-V amorphous ribbons.  

![Fig. 1](a) XRD and (b) DSC curves of Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ alloys ribbons produced by melt spinning at different spinning rates.
Figure 2 shows typical TEM and high-resolution transmission electron microscopy (HRTEM) images of the Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ alloy with spinning rates of 30 m s$^{-1}$ and 45 m s$^{-1}$. Figure 2a reveals that the surface is uneven and has gray and black areas in the amorphous matrix. The HRTEM image shows a disordered structure with about 80-nm black nano-regions in the amorphous matrix. The EDX analysis confirmed that there were differences in chemical composition in the I, II, and III regions. It was observed that the concentration profile of different elements showed diverse trends. At the black nano-region, the Ni content was highest and the Ti and Zr content was lower than in other areas when the spinning rate was 30 m s$^{-1}$. This means that there was a segregation of Ni in this region, while Ti and Zr were diluted during the melt-spinning process of Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ alloy. Combined with Fig. 2a, c and Table I, the composition of the amorphous alloy was inhomogeneous when the spinning rate was 30 m s$^{-1}$.

As shown in Fig. 2b, when the spinning rate reached 45 m s$^{-1}$, the surface was even and flat. The corresponding selected-area diffraction patterns for region B are displayed in the inset of Fig. 2b, which shows only the amorphous ring, confirming the presence of an amorphous structure. Figure 2d shows that the surface of the melt-spun ribbons was flat. And the disordered atomic arrangement indicated that the matrix was a homogeneous amorphous structure. The EDX analysis confirmed that the chemical composition in the IV region was the same as the nominal composition when the spinning rate was 45 m s$^{-1}$. Compared with the spinning rate of 30 m s$^{-1}$, EDX confirmed that the chemical composition was more uniform and that the amorphous structures of melt-spun ribbons were more homogeneous and showed a fully disordered structure when the spinning rate reached 45 m s$^{-1}$. Therefore, the melt-spun ribbons had a more homogeneous amorphous structure with an increase

Table I The chemical composition of Ti$_{47}$Zr$_{31}$Ni$_{14}$Cr$_{8}$ alloy in atomic percentage

| Region | Ti (at.%) | Zr (at.%) | Ni (at.%) | Cr (at.%) |
|--------|-----------|-----------|-----------|-----------|
| I      | 42.6±0.03 | 23.7±0.03 | 21.5±0.03 | 12.2±0.03 |
| II     | 42.0±0.03 | 22.4±0.03 | 26.8±0.03 | 8.8±0.03  |
| III    | 47.0±0.03 | 31.6±0.03 | 13.7±0.03 | 7.7±0.03  |
| IV     | 46.8±0.03 | 31.2±0.03 | 13.9±0.03 | 8.1±0.03  |
in the spinning rate. This consistency with the XRD and DSC results provides further confirmation that the melt-spun ribbons were amorphous when the spinning rate reached 45 m s⁻¹.

Figure 3a shows the Zwick electronic universal testing machine and the schematic diagram of the location during stretching. Figure 3b displays a dimension diagram of a tensile melt-spun ribbon with length of 55 mm, width of 4 mm, and thickness of 0.3 mm when the spinning rate was 30 m s⁻¹. Figure 3c presents the tensile stress–strain curves of amorphous ribbons under different spinning rates from 30 m s⁻¹ to 45 m s⁻¹. Table II shows that the tensile strength of amorphous ribbons increased significantly from 224 MPa at a spinning rate of 30 m s⁻¹ to 542 MPa at a spinning rate of 45 m s⁻¹. When the spinning rate was increased from 30 m s⁻¹ to 45 m s⁻¹, the elongation exhibited a small increasing tendency from 0.28% to 1.1%, and the elastic modulus decreased from 97.3 GPa to 44.6 GPa. Compared with other ribbons, the stress–strain curve revealed an interesting phenomenon: a series of stress drop phenomena began to appear over time when the spinning rate reached 45 m s⁻¹. This is a serrated flow behavior, which means a good toughness compared with ribbons of other spinning rates.

Figure 4 shows the physical morphology of the fractured surfaces of the samples at a spinning rate of 30 m s⁻¹ (Fig. 4a, c) and 45 m s⁻¹ (Fig. 4b, d). Figure 4a and c reveals that the fractured surface of ribbons exhibited a cleavage feature, which is the characteristic of brittle fracture. The reason is that with the increase of loading strain, the shear deformation occurs on the amorphous ribbons, resulting in highly localized strains. Finally, the brittle fracture occurs along a single shear zone.²⁶

Figure 4b and d shows that the fracture surface of ribbons exhibits a vein-like pattern which is attributed to a local change in viscosity along the shear zones. The main reason

| Spinning rate (m/s) | Tensile strength σb (MPa) | Elongation δ (%) | Elastic modulus E (GPa) |
|---------------------|---------------------------|------------------|------------------------|
| 30                  | 224±23                    | 0.28±0.03        | 97.3                   |
| 35                  | 318±25                    | 0.52±0.01        | 66.1                   |
| 40                  | 438±23                    | 0.71±0.01        | 62.1                   |
| 45                  | 542±22                    | 1.10±0.04        | 44.6                   |

Fig. 3 (a) Zwick electronic universal testing machine; (b) ribbon size diagram; (c) stress–strain curve obtained from Ti₄₇Zr₃₁Ni₁₄Cr₈ amorphous ribbons; (d) a schematic of a flow units model with different spinning rates.
is that during the stretching process, the flow units first enter the stochastic activation stage. With the increase in loading strain, an increasing number of flow units were gradually activated and coordinated movement between adjacent flow units. Finally, these activated flow units began to penetrate each other and connect as a whole, and multiple shear zones were formed. The shear zone moves under stress, and when it encounters the elastic matrix, the motion is blocked. When the local stress of the elastic matrix exceeds a certain stress, the shear zone will continue to move beyond the elastic matrix. This local change in viscosity along the shear zones results in serrated flow and a macroscopic decrease in stress.

As the shear zone increased, a series of stress drop phenomena began to appear over time, resulting in a serrated flow phenomenon (Fig. 3c, inset). The results indicated that the flow units increase with the increase in the spinning rate in the amorphous ribbons. The flow unit model with different spinning rates is shown in Fig. 3d. It was also found that the mechanical properties and the plasticity of the amorphous ribbons were improved by increasing the spinning rate during the melt-spinning process.

Since amorphous alloys have good application prospects in hydrogen absorption, hydrogen absorption properties of amorphous alloys have been studied. The amorphous ribbons must be activated before hydrogen absorption. Activation means that the passivated surface that does not absorb gas becomes a fresh surface that can absorb gas again after being activated at high temperature in vacuum. The activation temperature must be below the glass transition temperature to ensure that the ribbons are still amorphous. Thus, according to the DSC curves, the activation temperature of the amorphous ribbons were determined to be 473 K. Figure 6 shows that the phase structure before and after the amorphous ribbon activation remained consistent. Hydrogen absorption/desorption kinetic curves of amorphous ribbons after activation at 473 K under vacuum for 2 h are shown in Fig. 5.

Fig. 5 Hydrogen absorption/desorption kinetics curves of Ti47Zr31Ni14Cr8 amorphous ribbons at the spinning rate of 45 m/s−1.
Spinning rates have been systematically investigated. When 45 m s⁻¹, the tensile strength, elongation, and elastic moduli of Ti₄₇Zr₃₁Ni₁₄Cr₈ amorphous ribbons with different spinning rates increased, and the hydrogenation kinetics and hydrogen desorption capacity were improved. After the samples absorbed a large amount of hydrogen, the formation of crystalline phase of ZrH₂, TiH₂, and (ZrTi)₂Ni₇ phases resulted in the loss of mechanical properties, which was mainly because hydrogen promotes the decomposition of phases and the formation of new phases.

Conclusions

In the present work, the mechanical properties, fracture mechanism, and hydrogen absorption/desorption properties of Ti₁₇Zr₃₁Ni₁₄Cr₈ amorphous ribbons with different spinning rates have been systematically investigated. When the spinning rate was greater than or equal to 30 m s⁻¹, the alloys showed amorphous structure. With the spinning rate increased, the amorphous ribbons became more homogeneous. When the spinning rate was increased from 30 m s⁻¹ to 45 m s⁻¹, the tensile strength, elongation, and elastic modulus changed from 224 MPa, 0.28%, and 97.3 GPa to 542 MPa, 1.1%, and 44.6 GPa, respectively.

The fractured surface of ribbons exhibited a cleavage feature when the spinning rate was 30 m s⁻¹. The fracture surface of the melt-spun ribbons at 45 m s⁻¹ exhibited a vein-like pattern, which came from the interaction between the elastic matrix and the shear zones. These features provide better mechanical properties. With an increase in the flow units, the hydrogenation kinetics and hydrogen desorption capacity were improved. After the samples absorbed a large amount of hydrogen, the formation of crystalline phase of ZrH₂, TiH₂, and (ZrTi)₂Ni₇ phases resulted in the loss of mechanical properties, which was mainly because hydrogen promotes the decomposition of phases and the formation of new phases.
