Abstract In this study, the atmospheric component of a state-of-the-art climate model (HadGEM2-ES) that includes earth system components such as interactive chemistry and eight species of tropospheric aerosols considering aerosol direct, indirect, and semi-direct effects, has been used to investigate the impacts of local and non-local emissions of anthropogenic sulphur dioxide on the East Asian summer monsoon (EASM). The study focuses on the fast responses (including land surface feedbacks, but without sea surface temperature feedbacks) to sudden changes in emissions from Asia and Europe. The initial responses, over days 1–40, to Asian and European emissions show large differences. The response to Asian emissions involves a direct impact on the sulphate burden over Asia, with immediate consequences for the shortwave energy budget through aerosol–radiation and aerosol–cloud interactions. These changes lead to cooling of East Asia and a weakening of the EASM. In contrast, European emissions have no significant impact on the sulphate burden over Asia, but they induce mid-tropospheric cooling and drying over the European sector. Subsequently, however, this cold and dry anomaly is advected into Asia, where it induces atmospheric and surface feedbacks over Asia and the Western North Pacific (WNP), which also weaken the EASM. In spite of very different perturbations to the local aerosol burden in response to Asian and European sulphur dioxide emissions, the large scale pattern of changes in land–sea thermal contrast, atmospheric circulation and local precipitation over East Asia from days 40 onward exhibits similar structures, indicating a preferred response, and suggesting that emissions from both regions likely contributed to the observed weakening of the EASM. Cooling and drying of the troposphere over Asia, together with warming and moistening over the WNP, reduces the land–sea thermal contrast between the Asian continent and surrounding oceans. This leads to high sea level pressure (SLP) anomalies over Asia and low SLP anomalies over the WNP, associated with a weakened EASM. In response to emissions from both regions warming and moistening over the WNP plays an important role and determines the time scale of the response.

Keywords East Asian summer monsoon · Aerosol–radiation and aerosol–cloud interactions · Land–sea thermal contrast · Fast responses

1 Introduction

The East Asian summer monsoon (EASM), driven by temperature differences between the Asian continent and the Indian and Pacific Oceans, influences the climate in most East Asian countries (Webster 1987; Tao and Chen 1987). Since the late 1970s, the EASM has exhibited a considerable weakening trend, and a southward shift of the main rain belt, known as the southern flooding and northern drought (SFND) pattern (Yu et al. 2004; Yang and Zhu 2008; Ding et al. 2008, 2009; Wang et al. 2013). This change of the EASM has been suggested to be caused by many factors (Zhou et al. 2009), including sea surface temperature (SST) variability (Yang and Zhu 2008; Li et al. 2010; Fu...
and Li 2013), decadal changes in sensible heat flux over the Tibetan Plateau (Ding et al. 2009; Duan et al. 2013), anthropogenic aerosol (Xu 2001; Menon et al. 2002; Huang et al. 2007; Liu et al. 2009, 2011; Chen et al. 2012; Zhang et al. 2012; Guo et al. 2013; Hwang et al. 2013; Jiang et al. 2013; Ye et al. 2013; Wang et al. 2013; Zhou et al. 2013; Polson et al. 2014; Song et al. 2014), and natural decadal variability (Lei et al. 2011).

East Asia, especially East China is one of the most polluted regions in the world because of its rapid economic development in recent decades. Total anthropogenic emissions of sulphur dioxide (SO₂), the source gas for sulphate development in recent decades. Total anthropogenic emissions of sulphur dioxide (SO₂), the source gas for sulphate development in recent decades.

The atmospheric resolution is N96 (1.875° by 1.25°) with 38 vertical levels with the model top at ∼39 km.

The model used is the atmospheric component of the UK Met Office Hadley Centre Earth system model HadGEM2-ES (Collins et al. 2011; Jones et al. 2011; Bellouin et al. 2011). The atmospheric resolution is N96 (1.875° by 1.25°) with 38 vertical levels with the model top at ∼39 km.
HadGEM2-ES includes an interactive land and ocean carbon cycle as well as a dynamic vegetation model. The model includes earth system components such as an interactive tropospheric chemistry scheme and eight species of tropospheric aerosols, including ammonium sulphate, mineral dust, sea salt, fossil fuel black carbon, fossil fuel organic carbon, biomass burning aerosols, secondary organic and ammonium nitrate aerosols. The direct radiative effect due to scattering and absorption of radiation by all eight aerosol species represented in the model is included. The semidirect effect, whereby aerosol absorption tends to change cloud formation by warming the aerosol layer, is included implicitly. The parameterization of the indirect effects is described in detail by Jones et al. (2001). The CDNC is calculated from the number concentration of the accumulation and dissolved modes of hygroscopic aerosols. For the first indirect effect, the radiation scheme uses the CDNC to obtain the cloud droplet effective radius (CDER). For the second indirect effects, the large scale precipitation scheme uses the CDNC to compute the autoconversion rate of cloud water to rainwater. The detailed descriptions of the aerosol module are given in Bellouin et al. (2011). The historical emissions for tropospheric aerosols and aerosol precursors are described by Lamarque et al. (2010). Data sets required by HadGEM2-ES for tropospheric aerosol modelling are emissions of sulphur dioxide (SO₂), land-based dimethyl sulphide (DMS), ammonia (NH₃), and primary black and organic carbon aerosols from fossil fuel combustion and biomass burning. Emissions of sea-salt, mineral dust, and ocean-based DMS, are computed interactively. HadGEM2-ES participates in the CMIP5 simulations and the validation of model aerosols and their radiative forcing has been documented in Bellouin et al. (2011).

Figure 1 shows the annual mean sulphur dioxide emissions in 2000 (Lamarque et al. 2010). South and East Asia, Western Europe, and the east coast of USA are the stronger emission regions. The same experiments as performed in Dong et al. (2014) are used in this study to investigate the responses of the EASM to sudden changes in Asian and European sulphur dioxide emissions, and they are summarized in Table 1. The CONTROL experiment is forced by monthly climatological SST and sea ice averaged over the period of 1986–2005 from HadISST (Rayner et al. 2003), with well mixed greenhouse gas concentrations and all species of aerosol and related emissions as in 2000. The sulphur dioxide emissions have seasonal cycles, but they are very weak (not shown). Two sensitivity experiments, NO-ASIA and NO-EUROPE, have been performed in which the sulphur dioxide emissions over Asia or Europe have been removed, respectively, everything else remaining as in the CONTROL.

In order to separate externally forced variability from internal variability and to study transient adjustment processes, an ensemble of 30 integrations, each 3 months long starting from 1st June with daily outputs, differing only in their initial conditions, is performed for each experiment (e.g., Dong et al. 2014). The same 30 sets of initial conditions are used for each experiment. June 1–30 from the 5th year of a spin-up integration are taken as 30 different June 1 initial conditions in the 30 ensemble integrations. The spin-up integration is forced with climatological SST and sea ice, and with well mixed greenhouse gases concentrations and all species of aerosol emissions at 2000 values. The response to Asian and European sulphur dioxide emissions is estimated as the difference between the ensemble means of the CONTROL and NO-ASIA experiments, and

Table 1 Summary of numerical experiments

| Experiments  | Boundary conditions                                                                 | Transient experiments (for June, July, and August) |
|--------------|--------------------------------------------------------------------------------------|---------------------------------------------------|
| CONTROL      | Monthly climatological SST and sea ice averaged over the period of 1986–2005 using HadISST (Rayner et al. 2003). Sulphur dioxide, soot, biogenic aerosols, biomass-burning, fossil fuels organic carbon at 2000 emissions. Greenhouse gases concentrations at 2000. No natural forcing variation (e.g., solar, volcanic) | 30 members                                        |
| NO-ASIA      | As in CONTROL, but without anthropogenic sulphur dioxide emissions over Asia          | 30 members                                        |
| NO-EUROPE    | As in CONTROL, but without anthropogenic sulphur dioxide emissions over Europe       | 30 members                                        |
the CONTROL and NO-EUROPE experiments, respectively. The ensemble mean across 30 members to a large extent removes the model’s internal variability and allows for an assessment of the daily adjustment of the atmospheric circulation and land surface processes.

2.2 Model climate over East Asia

In this section some climatological features of the CONTROL experiment are compared with observed features. Figure 2a, b shows the observed rainfall based on GPCP (Adler et al. 2003), sea level pressure (SLP) of HadSLP2 (Allan and Ansell 2006) and 850 hPa wind distribution based on NCEP reanalysis (Kalnay et al. 1996), whereas Fig. 2c, d shows the corresponding model climatologies.

The model reproduces the spatial pattern of the East Asian summer climate fairly well (Fig. 2), suggesting that it is appropriate for use in the investigation of the response of the EASM to anthropogenic sulphate aerosols. In observations, the existence of the subtropical anticyclone over the North Pacific causes south-westerlies from the Indian Ocean and easterlies from the tropical Pacific Ocean to converge around the Philippines, becoming a strong southerly (Fig. 2b). This southerly flow transports a large amount of water vapor into East Asia. The anticyclonic circulation in the subtropics over the WNP and south-westerlies over eastern China, Korea and Japan along the western and northern fringes of this anticyclonic circulation are reasonably well reproduced in the model (Fig. 2d). However, the westerly from the Indian Ocean is stronger over the Philippines and it extends too far east into the WNP. The monsoon trough also extends too far to the east, and the southerly from the South China Sea is relatively weak in the model simulation (Fig. 2d). The weaker southerly in the model is associated with a weak subtropical high over the WNP. The stronger convergence over the Philippines and the tropical WNP in model is also consistent with stronger WNP. The stronger convergence over the Philippines and it extends too far east into the WNP. The weaker southerly in the model simulation (Fig. 2d). The weaker southerly in the model is associated with a weak subtropical high over the WNP. The stronger convergence over the Philippines and the tropical WNP in model is also consistent with stronger local rainfall (Fig. 2c).

Compared to observations (Fig. 2a), the model simulation shows a relative lack of precipitation over central India, the Western Ghats, and an extensive area over the western Bay of Bengal. It overestimates precipitation over the western equatorial Indian Ocean and the Himalayan foothills (Fig. 2c). Convection tends to be favoured over these latter regions due to the large availability of moisture and heat over the equatorial Indian Ocean and the orographic forcing as the low-level monsoon flow hits the Himalayan foothills respectively. This excessive equatorial Indian Ocean rainfall appears to be an inherent feature of the Met Office Unified model, with preferential model convection over areas with large amounts of available heat and moisture (Martin et al. 2010). This bias is also found in other versions of the Met Office Hadley Centre Global Environmental Model (Levine and Turner 2012; Guo et al. 2013). Despite these deficiencies, the simulated precipitation over East Asia compares fairly well with observations with an area averaged model precipitation of 2.99 mm day$^{-1}$ over North China (35°N–45°N, 100°E–125°E) and 8.93 mm day$^{-1}$ over South China (22.5°N–32.5°N, 100°E–120°E), in comparison with area averaged values of 2.70 and 6.58 mm day$^{-1}$ in observations (Fig. 2a, c).

2.3 Observed trends over East Asia

Linear trends in precipitation (CRUTS3.21, Harris et al. 2014), SLP (HadSLP2, Allan and Ansell 2006) and 850 hPa winds (NCEP/NCAR reanalysis, Kalnay et al. 1996) for 1950–2012 are shown in Fig. 2e, f. The circulation trends are characterized by positive SLP anomalies (0.8–1.6 hPa) over East Asia, being associated with anomalous northeasterlies along the east coast of Asia and weakened cross-equatorial flow from Southeast Asia, indicating a weakening of the EASM. Associated with these circulation anomalies is a dipole pattern of precipitation trends over East Asia with a decrease of 0.2–0.8 mm day$^{-1}$ over North China and an increase of 0.2–1.6 mm day$^{-1}$ over South China. The area averaged decrease over North China (35°N–45°N, 100°E–125°E) is 0.33 mm day$^{-1}$ and the area averaged increase over South China (22.5°N–32.5°N, 100°E–120°E) is 0.29 mm day$^{-1}$ and this is the SFND pattern revealed in many previous studies (e.g. Ding et al. 2008, 2009; Zhao et al. 2010; Wang et al. 2013).

3 Seasonal mean responses to local and non-local sulphur dioxide emissions

3.1 Seasonal mean changes of aerosol burden

The June, July, and August mean changes in aerosol burdens in response to Asian and European sulphur dioxide emissions are illustrated in Fig. 3. Asian emissions lead to localized increases in sulphate burden over the emission area (Fig. 3a). The downstream increases over the WNP are similar to the sulphate burden changes seen between present day and preindustrial conditions in the GISS model (e.g. Bauer and Menon 2012). The increased sulphate burden results in a 60–80 % increase in CDNC (Fig. 3c) and a 10–20 % decrease in CDER over the emission region (Fig. 3e), and a 10–20 % increase in CDNC and a 2.5–5 % decrease in CDER downstream over the WNP.

European emissions induce large increases in sulphate burden not only over Europe, but also downstream over some parts of Asia, Africa, and the tropical Atlantic Ocean (Fig. 3b). Associated with these increases in sulphate burden are increases in CDNC by more than 80 % and decreases in CDER by 10–20 % over Europe and the
Mediterranean, 10–20 % increases in CDNC over the tropical Atlantic and African monsoon region, the Arabian Sea, south and southeastern Asia, and the WNP and decreases in CDER by 2.5–10 % (Fig. 3d, f). The changes over south Asia and the WNP are mainly due to advection there by westerly monsoon circulation.

3.2 Seasonal mean responses of the EASM and precipitation

The seasonal mean changes in surface air temperature (SAT), SLP, 850 hPa winds, and precipitation in response to Asian and European sulphur dioxide emissions are
illustrated in Fig. 4. Asian emissions lead to a decrease in SAT (~0.2–0.4 °C) over a large area of Asia, accompanied by high pressure anomalies locally (Fig. 4c). Asian emissions also lead to anomalous low pressure over the WNP (Fig. 4c). This dipole pattern of SLP anomalies is opposite to the summer mean pattern, indicating a weakening of the land–sea pressure gradient. This is associated with anomalous north-easterlies along the eastern coast of East Asia (Fig. 4c), indicating a weakening of summer climatological south-westerlies, which results in a decrease (~0.4–1.2 mm day⁻¹) in precipitation over East Asia, and an increase to the south and over the WNP (Fig. 4e).

Despite only inducing a small change in the sulphate burden over Asia, European emissions also lead to a significant surface cooling over Asia and a dipole pattern of SLP anomalies, characterized by an anomalous high over Asia and an anomalous low over the WNP. This is similar in structure to the dipole pattern of SLP anomalies that results from Asian emissions, but the magnitude of the anomalous low over the WNP in response to European emissions
is larger. This dipole pattern of SLP anomalies is again associated with anomalous north-easterlies along the coast of East Asia (Fig. 4d), indicating a weakening of summer south-westerlies. Associated with these circulation anomalies are a decrease (~0.4–0.8 mm day$^{-1}$) in precipitation over East Asia and an increase (0.4–1.2 mm day$^{-1}$) to the south and over the WNP (Fig. 4f). The main features of the weakening EASM circulation induced by both Asian and European emissions are anomalous high pressure over Asia and anomalous low pressure over the WNP. The results suggest a remote response of the EASM to European emissions and indicate a preferred response of the EASM to local and non-local anthropogenic sulphur dioxide emissions. Note that, in contrast to the response to Asian emissions, changes in sulphate burden, CDNC and CDER in response to European emissions are very small over Asia (Fig. 3); this contrast implies that different processes are involved in producing the climate impacts.

Fig. 4 The spatial patterns of changes in surface air temperature (SAT, °C), SLP (hPa) and 850 hPa wind (m s$^{-1}$), and precipitation (mm day$^{-1}$) in response to Asian and European sulphur dioxide emissions in June, July, and August. Thick black lines highlight regions where the changes are statistically significant at the 90 % confidence level using a two-tailed Student’s $t$ test. The thick colour boxes highlight regions where some indices are illustrated in Figs. 5 and 6.
4 Time evolution of the East Asian summer monsoon responses

Section 3.2 indicated that key features of the responses to both Asian and European sulphur dioxide emissions are: anomalous high pressure over Asia and anomalous low pressure over the WNP, associated with anomalous north-easterlies along the eastern coast of East Asia, indicating a weakening south-westerly EASM circulation. Interestingly this pattern is similar to the trends seen in observations (Fig. 2f). We now consider in more detail the mechanisms that lead to the weakened EASM by examining the time evolution of the response.

4.1 Fast adjustments

The time evolutions (5 day mean) of some EASM indices in response to a sudden change in regional sulphur dioxide emissions are illustrated in Fig. 5. These transient evolutions reveal that significant changes in the EASM occur from about day 40–50 onward, in response to both Asian and European emissions. The changes are characterized by a significant weakening of the tropospheric temperature difference between Asia and the WNP (Fig. 5a), weakening SLP difference between the WNP and Asia (Fig. 5b), and reduction in summer monsoon meridional wind (Fig. 5c). Associated with these changes in land–sea temperature contrast and circulation is a decrease in precipitation over East Asia (Fig. 5d), and an increase to the south and over the WNP (Fig. 5e).

Figures 6 and 7 show the development of the atmosphere and land surface responses over Asia (Note area averaged responses over Asia for a selection of variables for the 1–20 and 41–90 day means are given in Table 2). Aerosol–radiation and aerosol–cloud interactions in response to Asian emissions lead to a rapid increase in top of atmosphere (TOA) upward SW radiation (not shown) and therefore a decrease in TOA clear sky net SW and TOA net SW (Fig. 6c, d; Table 2) during the first 20 days. Changes in atmospheric SW absorption are very small (Table 2). As a result, the decrease in surface net SW is similar to the change at TOA (Fig. 6d, e; Table 2). The reduction in surface net SW radiation is partly compensated by a decrease in upward turbulent heat fluxes (Fig. 6g; Table 2), so there

![Fig. 5](image-url)
is little change in SAT (Fig. 6h). Thus, Asian sulphur dioxide emissions lead to significant changes in the local surface energy budget on a timescale of weeks. By contrast, European sulphur dioxide emissions do not affect sulphate burden (Fig. 3b) or sulphate AOD (Fig. 6a; Table 2) over Asia. As a result, in the first 20 days changes in TOA net SW (Fig. 6d) and therefore in surface net SW and LW (Fig. 6e, f; Table 2) are very small.

Fig. 6 The time evolutions of 5 day averaged ensemble mean changes over Asia (25°N–50°N, 75°E–115°E, green box in Fig. 4c) induced by Asian and European sulphur dioxide emissions in June, July, and August. a Sulphate AOD at 0.55 μm, b column integrated water vapor (kg m⁻²), c top of atmosphere (TOA) clear sky short-wave radiation (SW), d TOA SW, e surface SW, f surface LW, g surface sensible and latent heat flux, h surface air temperature (SAT, °C), and i air temperature at 500 hPa. Radiation and fluxes are in W m⁻² and positive values mean downward. Radiation is the net component. The thin lines show the N⁻¹/² of internal standard deviation in the GLOBAL experiment with the number of integrations N = 30.
surface energy budget (Fig. 6), including an increase in surface net SW of about 1.0 W m\(^{-2}\) and a decrease in surface net LW (Fig. 6e, f).

The EASM is driven by land–sea thermal contrast between the Asian continent and adjacent oceans (e.g., Webster 1987; Tao and Chen 1987; Zuo et al. 2012). Not only are changes over the Asian continent important, but also changes over the WNP, as illustrated in Fig. 4 for the seasonal mean changes. Time series of key variables over the WNP are illustrated in Fig. 8. There is hardly
any significant change in either temperature or water vapor in first 20 days in response to either Asian or European emissions (Fig. 8a–d). However, significant—albeit short-lived—changes occur around day 20, characterized by drying and cooling in the free troposphere, associated with anomalous high SLP (Fig. 8e), reduced deep
convection (Fig. 8g) and precipitation (Fig. 8h). This cooling and drying is associated with a meridional dipole SLP pattern in the eastern hemisphere with positive anomalies around 15°N–30°N and negative anomalies around 15°S–10°N (Fig. 9a, b) that result in moisture divergence over the WNP and moisture convergence over the tropical Indian Ocean and tropical western Pacific (Fig. 9c, d). Most importantly, the drying and cooling in the free troposphere over the WNP during days 20–40 (Fig. 8a–e) are similar in magnitude to the drying and cooling over Asia (Fig. 7). The changes in the land–sea thermal contrast in the troposphere are therefore small (Fig. 5a, b). As a result, changes in EASM circulation and associated precipitation are small during this period (Fig. 5c).

The phase relationship among different variables over the WNP from days 20 to 40 is interesting. The drying of the atmosphere around day 20 leads to increased upward latent heat flux from days 25–30 (Fig. 8f) due to enhanced evaporation (not shown), leading to a rapid increase in atmospheric water vapour from days 25 to 40, setting conditions for enhanced convection over the WNP.

As illustrated in Fig. 8, significant changes, opposite in sign to changes during days 20–30, occur over the WNP after about day 40 in response to both Asian and European emissions. These changes are characterized by rapid warming and moistening in the free troposphere (Fig. 8a–d), a decrease in SLP (Fig. 8e), an increase in upward latent flux (Fig. 8f), enhanced deep convection (increase in high cloud cover) and precipitation (Fig. 8g, h). These changes over the WNP indicate a strong local coupling among the changes in SLP, local evaporation, tropospheric moistening, convection, and tropospheric warming. The low SLP anomaly leads to enhanced evaporation due to strengthened westerlies, resulting atmospheric moistening, leading to enhanced convection, inducing warming in free troposphere, especially in the upper troposphere. This warming in turn favours further decrease in SLP locally, providing a positive feedback. The warming and moistening over the WNP, together with opposite changes over Asian continent weaken the land–sea thermal contrast, induce larger thermal contrast in the upper troposphere than in the lower troposphere and determine time scales for the significant EASM response. The results suggest an important role of the upper tropospheric land–sea thermal contrast for the response of the EASM, consistent with recent studies (e.g., Bayr and Dommenget 2013, Dai et al. 2013).

Figure 5 also reveals intraseasonal variability (ISV) of the EASM indices in response to either Asian or European emissions. This ISV is mainly associated with the variability over the WNP (Fig. 8), where observations also show large ISV in boreal summer (Wang et al. 2009). This ISV might result from feedbacks between free tropospheric
Preferred response of the East Asian summer monsoon to local and non-local anthropogenic...

As shown in Fig. 8, anomalously low SLP around day 50 over the WNP enhances upward latent heat flux (Fig. 8e, f), leading to tropospheric moistening (Fig. 8c, d), enhancing deep convection (Fig. 8g, h) and atmospheric warming (Fig. 8a, b). The increased precipitation reduces atmospheric moisture that tends to cool the atmosphere and leads to an increase in SLP, leading to oscillation on intraseasonal time scale (e.g., Grabowski 2006; Wang et al. 2009). However, understanding the detailed processes behind the ISV is beyond the scope of this paper. We now focus on the time-mean response during days 41–90, when significant weakening of the EASM occurs in response to both Asian and European emissions. This period dominates the seasonal mean responses.

### 4.2 Days 41–90 response to Asian emissions

The spatial patterns of time mean changes over days 41–90 of some key variables induced by Asian sulphur dioxide emissions are illustrated in Fig. 10 (see also Table 2). Asian emissions lead to localized increases in sulphate AOD over Asia of up to ~0.2 (Fig. 10a). The increase in direct scattering by the sulphate aerosols themselves, and the related increase in cloud albedo via aerosol cloud interactions leads to a localized decrease in TOA clear sky net SW...
radiation ($2$–$8$ W$^{-2}$) over Asia (Fig. 10b). The changes in surface net SW radiation show a reduction by $2$–$6$ W m$^{-2}$ (Fig. 10c), which is mainly related to changes in clear sky surface net SW (Table 2).

The reduction of surface net SW radiation over Asia, only part of which is compensated by a decrease in upward latent heat flux (Fig. 10d; Table 2), acts to cool the surface and free troposphere (Fig. 10e, f). Meanwhile, the upward latent heat flux over the WNP and tropical Indian Ocean increases, consistent with enhanced convection and precipitation (Fig. 10i) and the increase in tropospheric air temperature there (Fig. 10f). This distribution of temperature anomalies reduces meridional and zonal land–sea thermal contrasts, and is associated with high SLP anomalies over Asia and low SLP anomalies over the WNP, leading to anomalous northeasterlies over East Asia, weakening EASM (Fig. 10g), anomalous moisture transport divergence to anomalous northeasterlies over East Asia and a weakening over Asia and low SLP anomalies over the WNP, leading to anomalous northeasterlies over East China with anomalous moisture transport divergence to anomalous northeasterlies over East Asia and convergence to the South (Fig. 10h), and a decrease in precipitation ($0.4$–$1.6$ mm day$^{-1}$) over East Asia and an increase over the WNP and tropical Indian Ocean (Fig. 10i). Importantly, results in our study indicate that the warming resulting from the diabatic heating associated with enhanced deep convection over the WNP causes further reductions in the land–sea thermal contrast between Asia and the WNP, providing a positive feedback for the weakened EASM related to the cooling over land.

The patterns of changes in circulation and precipitation in response to Asian anthropogenic sulphur dioxide emissions bear some similarities to those demonstrated in recent studies by Liu et al. (2009) and Guo et al. (2013) in their multiyear equilibrium integrations using an atmospheric model with prescribed SSTs. Both those studies indicated that local anthropogenic sulphur dioxide emissions induce a weakening of the EASM and reduced precipitation in a large area over East Asia. Our transient simulations might not reach equilibrium with the forcing changes even at the end of the season and land surface responses to forcing changes in pre-monsoon season are not included in comparison to those in Liu et al. (2009) and Guo et al. (2013). However, the similarities in seasonal mean responses between this study and those in Liu et al. (2009) and Guo et al. (2013) indicate that the weakening of the EASM and reduced precipitation over East Asia in response to local sulphate aerosols are robust features in which the fast atmospheric and land surface responses on seasonal time scale may be the dominant processes.

### 4.3 Days 41–90 response to European emissions

The spatial patterns of time mean changes over days 41–90 of some key variables induced by European sulphur dioxide emissions are illustrated in Fig. 11. European emissions induce large increases in sulphate burden over Europe. However, the sulphate burden changes range from 0.1 to $1.0$ mg m$^{-2}$ over Asia, which is much smaller than those ($4$–$8$ mg m$^{-2}$) due to Asia emissions (Fig. 3a). Such small changes in sulphate burden, and therefore in CDNC and CDER, mean that changes in TOA clear sky net SW in response to European emissions are also very small over both central and East Asia (Table 2). However, there are significant decreases in column integrated water vapor over Asia and increases over the WNP (Fig. 11a).

The significant decrease in column integrated water vapor over Asia leads to a reduction in atmospheric heating by SW absorption (e.g., Mitchell et al. 1987), and an increase in surface clear sky net SW, and therefore surface net SW radiation (Fig. 11b; Table 2). The decreased water vapor concentration enhances radiative cooling to space, and therefore results in an increase in clear sky outgoing longwave radiation (a decrease in clear sky TOA LW) (Table 2). The decreased water vapor concentration also reduces the LW radiative cooling of the atmosphere to the surface, leading to a decrease in net surface LW over Asia (Fig. 11c; Table 2). The decrease in cloud cover associated with the reduced water vapor gives rise positive SW cloud radiative effect (CRE) and negative LW CRE (Table 2), leading to large changes in the net SW and LW than the clear sky net SW and LW at both TOA and surface (Table 2). The water vapor feedback may also contribute to a strengthening in the tropospheric cooling over Asia as demonstrated by previous studies (Soden et al. 2002; Gettelman and Fu 2008; Minschwaner et al. 2006). The opposite changes occur over the tropical Indian Ocean and the WNP related to moistening.

The reduction in surface net LW and enhanced upward sensible heat flux (Fig. 11c; Table 2) gives rise to a decrease in surface air temperature over Asia. The cooling at the surface and in the troposphere over Asia, together with warm mid-tropospheric temperature anomalies over the WNP reduces meridional and zonal land–sea thermal contrasts (Fig. 11e, f). This is associated with high SLP anomalies over Asia and low SLP anomalies over the WNP, leading to anomalous northeasterlies over East Asia and a weakening EASM (Fig. 11g). The weakened EASM leads to anomalous moisture transport divergence over East China with reduced convection, anomalous moisture transport convergence and enhanced convection over the WNP and tropical Indian Ocean (Fig. 11h, i). It is interesting to note that, perhaps surprisingly, the circulation response to European emissions is stronger than the response to Asian emissions.

The results above indicate that the tropospheric cooling and drying over Asia in response to European emissions is an important factor for the weakened EASM. This cooling and drying is not induced by changes in local sulphate burden, so what are the processes responsible? Shown in Fig. 12 are time-longitude evolutions of meridionally...
averaged temperature and water vapor over the latitude 25°-50°N in response to European emissions. Figure 12a shows that coherent surface cooling develops in 2-3 weeks in response to European emissions and the surface cooling is confined mainly to the west of 50°E. In contrast, time evolutions of changes in both mid-tropospheric temperature and water vapor show eastward propagation features (Fig. 12b, c). The cooling and drying over Europe induced by European emissions propagates downstream into Asia on a time scale of 2-3 weeks. This gives a propagation speed of 3.4-4.4 m s\(^{-1}\) and it is comparable to the area-averaged 500 hPa zonal wind of 4.2 m s\(^{-1}\), suggesting a dominant role of advection of anomalous temperature and water vapor by mean flow. These temperature and water vapour anomalies then induce the local feedbacks seen in Fig. 11.

5 Conclusions

In this study, we have investigated the impacts of regional sulphur dioxide emissions on the EASM through its impacts on the atmosphere and the surface with an atmospheric general circulation model, excluding SST feedbacks. We examined the transient adjustment processes of the surface and troposphere when either Asian or European emissions.
sulphur dioxide emissions are turned on suddenly. The major processes are summarised schematically in Fig. 13.

- The response to Asian emissions involves a direct impact on the sulphate burden over Asia, with immediate consequences for the SW energy budget. Anthropogenic sulphate reduces the SW reaching the surface and induces a cooling at the land surface by directly scattering the solar radiation (aerosol–radiation interaction), and indirectly increasing the CDNC and decreasing CDER (aerosol–cloud interaction). The cooling at the land surface increases the atmospheric stability, suppresses the convection over East Asia, and reduces the condensational heating from convection. This leads to the free tropospheric cooling over Asia.
- European emissions have no significant impact on the sulphate burden over Asia. However, European emissions induce mid-tropospheric cooling and drying over the European sector. This cooling and drying anomaly is advected into Asia, and induces atmospheric and surface feedbacks.
- The circulation changes in response to both Asian and European emissions are characterized by high SLP anomalies over Asia and low SLP anomalies over the WNP. Cooling and drying of the troposphere over Asia and warming and moistening over the WNP reduce land–sea thermal contrast between Asia and the WNP, causing the weakened EASM circulation. In particular, the warming and moistening over the WNP determines the time scale of EASM response and enhances the changes in land–sea thermal contrast induced by changes over Asian continent either through Asian emissions or European emissions. The weakened EASM leads to a reduction in moisture transport convergence from ocean to land, a decrease in precipitation over East Asia, and an increase over the adjacent oceans.
- The changes in land–sea thermal contrast, atmospheric circulation and local precipitation over East Asia in response to either Asian or European emissions exhibit similar spatial structures and time evolutions, indicating a preferred response.

The results suggest that changes in aerosol emissions over Asia and Europe both influence thermal contrast between Asia and the WNP, affecting the strength of the EASM. This preferred response occurs despite very different perturbations to local aerosols burden in two cases, highlighting the importance of changes in both local and non-local aerosol emissions on the EASM. The impact of local aerosol emissions on the EASM is consistent with the studies of Liu et al. (2009) and Guo et al. (2013) and the non-local impact is in line with Cowan and Cai (2011). Our experiments were deliberately simplified to exclude feedbacks involving changes in sea surface temperatures (SST). Nevertheless it is interesting that the responses to both Asian and European sulphur dioxide emissions we found show some similarities to observed trends in circulation and precipitation during the last 6 decades (Fig. 2f and e) despite some distinct differences. The centre of positive SLP anomalies in the model responses is located near (30°N, 110°E), which is further south than in the observed trends. The model responses include a negative SLP anomaly over the WNP while observations show little trend there. However, SLP
trends over the WNP in observations are sensitive to the specific time period considered, for example Song et al. (2014) show negative SLP trends in this region over the period 1958–2001. The area averaged trend of precipitation over North China (35°N–45°N, 100°E–125°E) is a decrease of 0.33 mm day\(^{-1}\) in observations during the last 6 decades. The model responses over the same region show a decrease in precipitation of 0.17 mm day\(^{-1}\) due to Asian sulphur dioxide emissions and a decrease of 0.23 mm day\(^{-1}\) due to European emissions. The similarities between the responses and observed trends support the idea that sulphate aerosol emissions contributed to the observed decline in precipitation over North China (e.g., Xu 2001; Menon et al. 2002, Liu et al. 2011, Chen et al. 2012, Guo et al. 2013, Jiang et al. 2013, Wang et al. 2013, Polson et al. 2014; Song et al. 2014) and that this decline is associated with tropospheric cooling and drying over Asia (e.g., Yu et al. 2004, Yu and Zhou 2007). Our results further suggest that both Asian and European emissions might have played a role. However, the model responses to local and non-local sulphur dioxide emissions do not show the increase in precipitation over South China as observations indicate, suggesting that other drivers rather than direct impact of the sulphate aerosols through aerosol–radiation and aerosol–cloud interactions might be the main factors for the enhanced precipitation over South China during the last 6 decades.

European emissions of anthropogenic aerosol precursor are decreasing following changes to the Clean Air Acts in the United States and Europe in the early 1990s, while Asian emissions are increasing (e.g., Lamarque et al. 2010). Understanding the roles of these regional changes in anthropogenic aerosol precursor emissions is important for predicting future decadal-scale changes in the EASM. It is highly likely that SST feedbacks will both amplify the responses and modify the pattern (e.g., Ganguly et al. 2012). The SST feedbacks are expected to evolve on timescales of months to decades, longer than those considered in this study. Understanding how these SST feedbacks resulting from local and non-local aerosol emissions modify the relatively fast processes is an important area for future work.
