Abstract

Using a macroscopic analysis, we demonstrate that time-dependent noncollinear spin transport may show a wavelike character. This leads to modifications of pure spin-diffusion dynamics and allows one to extract a finite spin-signal propagation velocity. We numerically study the dynamics of a pure spin current pumped into a nonmagnetic layer for precession frequencies ranging from GHz to THz.

I. INTRODUCTION

Transporting information encoded in electronic spins through layers of ferromagnetic and normal metals is a central theme of magnetoelectronics. Structures, in which all spins are essentially collinear, i.e., parallel or antiparallel, have been thoroughly investigated in experimental and theoretical studies. The quasi-static properties for the special case of structures with collinear spin and magnetization directions where the spin-polarized current flows perpendicularly to the plane of the layers can be analyzed in terms of a scalar space-dependent spin accumulation for up and down spins. The functionality of collinear magnetoresistive structures can be enhanced by including tunneling elements. Although collinear spin transport is of importance for certain variants of giant and tunneling magnetoresistance effects, a non-collinear alignment of spin and magnetization orientations leads to additional degrees of freedom for the manipulation of spin angular momentum and has attracted much attention in recent years. For instance, one can exploit the angular dependence of the giant magnetoresistance effect, or can change the alignment of spins by spin currents, leading to the phenomenon of spin transfer torque and potential novel applications. A different method to exploit the freedom of noncollinear spin orientations in magnetic multilayers is the use of magnetization precession in a ferromagnetic layer, which “pumps” a spin current into an adjacent nonmagnetic metal. A precessing magnetization, which is necessary for spin pumping, creates the need to deal with a time-dependent orientation of the spins in the whole multilayer, so that it becomes essential to study dynamical noncollinear spin transport problems.

We are concerned with a theoretical analysis of the propagation of signals encoded in a spin current, which flows through a multilayer structure with noncollinear magnetization and spin directions. Most investigations of time-dependent noncollinear spin transport are based on the Bloch-Torrey diffusion equations for the nonequilibrium magnetization or spin accumulation. These equations essentially describe spin transport as a diffusion process and therefore show the same problem as the spin diffusion equation for collinear spins: no finite propagation velocity for a spin signal can be defined because the diffusion equation leads to a finite spin current density everywhere as soon as there is a source. Recently, we showed that this difficulty can be resolved for collinear spin transport by using a “telegraph” equation, which generalizes the diffusion equation, and leads to noticeable differences from
the diffusion equation results for frequencies exceeding several 100 GHz for metals such as copper. Importantly, the telegraph equation shows a wave-diffusion duality, which enables one to define a finite propagation velocity for the spin signal. In this paper, we use a similar treatment for noncollinear spin transport to show how a finite signal propagation velocity arises in this case. We predict that noncollinear spin transport at high frequencies shows a dynamics that is more complicated than what is expected from an analysis using the spin-diffusion equation. We numerically analyze the propagation of a spin current pumped into a nonmagnetic metal by a precessing magnetization in an adjacent ferromagnetic layer.

This paper is organized as follows. In Sec. II, we present the macroscopic dynamical equations governing noncollinear spin transport. In Sec. III, the dynamical equations are combined into a telegraph equation, which is studied analytically to discuss qualitative aspects of dynamical noncollinear spin-transport. In Sec. IV, we solve numerically the dynamical equations for the spin transport, and the main conclusions are summarized in Sec. V.

II. DYNAMICAL EQUATIONS

In nonmagnetic conductors and some ferromagnetic metals, the dynamics of conduction electrons under the influence of external fields can be described by a generalized semiclassical Boltzmann equation,

\[
\begin{align*}
\frac{i\hbar}{\partial t} & \hat{\rho} + \frac{i}{2} \left\{ \frac{\partial \hat{\varepsilon}}{\partial \vec{k}}, \frac{\partial \hat{\rho}}{\partial \vec{r}} \right\} - \frac{i}{2} \left\{ \frac{\partial \hat{\varepsilon}}{\partial \vec{r}}, \frac{\partial \hat{\rho}}{\partial \vec{k}} \right\} = [\hat{\varepsilon}, \hat{\rho}] + i\hbar \left. \frac{\partial \hat{\rho}}{\partial t} \right|_{\text{col}},
\end{align*}
\]

which we take as the starting point for our analysis of time-dependent noncollinear electron-spin transport in these systems. In Eq. (1), \( \hat{\rho}(\vec{r}, \vec{k}, t) \) is the single particle density matrix in spin space,

\[
\hat{\rho} = \begin{pmatrix}
\rho_{\uparrow\uparrow} & \rho_{\uparrow\downarrow} \\
\rho_{\downarrow\uparrow} & \rho_{\downarrow\downarrow}
\end{pmatrix},
\]

\( \hat{\varepsilon}(\vec{r}, \vec{k}, t) \) is the effective single-particle energy matrix, and \{\cdot, \cdot\} and [\cdot, \cdot] denote respectively the anticommutator and commutator for matrices in spin space. For completeness, we remark that in Eq. (2), the single-particle density matrix

\[
\rho_{ss'}(\vec{r}, \vec{k}, t) = \frac{V}{(2\pi)^3} \int d^3q e^{i\vec{q} \cdot \vec{r}} \langle c_{\vec{k}-\vec{q}/2,s}^+ c_{\vec{k}+\vec{q}/2,s'} \rangle,
\]
is defined by a statistical average over creation and annihilation operators \( c^\dagger \) and \( c \), with normalization volume \( V \). The diagonal matrix elements \( \rho_{\uparrow\uparrow} \) and \( \rho_{\downarrow\downarrow} \) are the electron distribution functions of the spin-up and spin-down, respectively, whereas the off-diagonal elements \( \rho_{\uparrow\downarrow} = \rho_{\downarrow\uparrow}^\ast \) represent the spin coherence\(^{25}\). Because the unit matrix \( \hat{I} \) and the Pauli matrices \( \hat{\sigma}_x, \hat{\sigma}_y, \hat{\sigma}_z \) form a basis for \( 2 \times 2 \) matrices, the spin-density matrix \( \hat{\rho} \) can be represented by
\[
\hat{\rho} = \left( \frac{1}{2} \right) \left[ (\rho_{\uparrow\uparrow} + \rho_{\downarrow\downarrow}) \hat{I} + \vec{u} \cdot \hat{\vec{\sigma}} \right],
\]
where \( \vec{u} = \text{Tr}(\hat{\sigma} \hat{\rho}) = (2\text{Re}\rho_{\uparrow\downarrow}, -2\text{Im}\rho_{\uparrow\downarrow}, \rho_{\uparrow\uparrow} - \rho_{\downarrow\downarrow}) \) is the Bloch vector and \( \hat{\vec{\sigma}} \) the vector of Pauli matrices.

Before proceeding from Eq. (1) for the spin-density matrix to equations for macroscopic quantities, such as spin currents and spin accumulation, we list a few assumptions made about quantities occurring in Eq. (1). First, we consider only layered structures whose extensions perpendicular to the growth direction (\( x \) axis) are infinite, and we also assume that the electric fields \( \vec{E} = E\vec{x}/|\vec{x}| \) is oriented along the growth direction \( x \). Second, the effect of magnetic fields on the orbital motion of electrons is neglected. These magnetic fields include the static external magnetic field \( \vec{B}_s \) and the magnetic field generated by induction due to the time-dependent electric field \( \vec{E}(x, t) \). Third, an isotropic effective mass model for the spin-degenerate conduction electrons is used, i.e.,
\[
\varepsilon_k = \frac{\hbar^2 k^2}{2m^*} - e\phi(x, t),
\]
where \( k \) and \( v \) denote the the electron wave vector and velocity, respectively. Thus we have to deal with a spin density matrix \( \hat{\rho} \) that depends only on \( x \) and has cylindrical symmetry around the \( x \) axis in \( k \) space.

Finally, we make a relaxation-time approximation for the collision term\(^{27}\)
\[
\frac{\partial \hat{\rho}}{\partial t} \bigg|_{\text{col}} = -\frac{\hat{\rho} - \langle \hat{\rho} \rangle_a}{\tau} - \frac{\langle \hat{\rho} \rangle_a - (\hat{I}/2)\text{Tr}(\hat{\rho})_a}{T_1},
\]
where \( \tau \) and \( T_1 \) are the momentum and spin relaxation times, respectively. Moreover, \( \langle \hat{\rho} \rangle_a \equiv (4\pi)^{-1} \int d\Omega_k \hat{\rho} \) is the angular average in the momentum space. By using Eq. (4) for the collision term, we have assumed that the longitudinal spin relaxation time \( T_1 \) is equal to the transverse one \( T_2 \). The validity of this approximation is discussed in detail by Ref.\(^{16}\).

Note that \( T_1 \) in Eq. (1) is one half of \( \tau_{sf} \) used in Eq. (2) of Ref.\(^{27}\).

With above simplifications, the effective single-particle energy \( \hat{\varepsilon}(\vec{r}, \vec{k}, t) \) is simplified to
\[
\hat{\varepsilon}(x, |\vec{v}|, t) = \varepsilon_0 \hat{I} + \hat{\varepsilon}_s,
\]
where \( \varepsilon_0 = \frac{\hbar^2 k^2}{2m^*} - e\phi(x, t) \) and \( \hat{\varepsilon}_s = -\vec{\mu} \cdot \vec{B}_s = \mu_B \vec{\sigma} \cdot \vec{B}_s \). Therefore, Eq. (1) simplifies to
\[
\frac{\partial \hat{\rho}}{\partial t} + v_x \frac{\partial \hat{\rho}}{\partial x} - \frac{eE}{m^*} \frac{\partial \hat{\rho}}{\partial v_x} + \frac{1}{2}\gamma(|\vec{u} \times \vec{B}_s|) \cdot \vec{\sigma} = -\frac{\hat{\rho} - \langle \hat{\rho} \rangle_a}{\tau} - \frac{\langle \hat{\rho} \rangle_a - (\hat{I}/2)\text{Tr}(\hat{\rho})_a}{T_1},
\]
where $\gamma = g\mu_B/\hbar$ is the absolute value of the electron ($g \approx 2$) gyromagnetic ratio.

To derive macroscopic spin transport equations comparable with the Bloch-Torrey diffusion equation, we need to sum over the electron wave vector $\vec{k}$ or, equivalently, the velocity $\vec{v}$ in Eq. (5). We first derive an equation for the spin density by multiplying both sides of Eq. (5) by $\hat{\sigma}/V$, taking the trace, and summing over $\vec{v}$

$$\frac{\partial \vec{n}_s(x, t)}{\partial t} = -\gamma \vec{n}_s(x, t) \times \vec{B}_s - \frac{\vec{n}_s(x, t)}{T_1} - \frac{\partial \vec{j}_s(x, t)}{\partial x},$$

(6)

where $\vec{n}_s(x, t) = V^{-1} \sum_{\vec{v}} \text{Tr}(\sigma \hat{\rho}) = V^{-1} \sum_{\vec{v}} \vec{u}$ and $\vec{j}_s(x, t) = V^{-1} \sum_{\vec{v}} v_x \text{Tr}(\sigma \hat{\rho}) = V^{-1} \sum_{\vec{v}} v_x \vec{u}$ are the spin density and spin current density, respectively. For the spin current density, we multiply both sides of Eq. (5) by $v_x \hat{\sigma}/V$, take the trace, and sum over $\vec{v}$. Using the expansion (A2) for the velocity dependence of the spin density matrix and the procedure in Appendix A, we obtain

$$\vec{j}_s(x, t) = -D \frac{\partial \vec{n}_s(x, t)}{\partial x} - \mu E(x, t) \vec{n}_s(x, t) - \tau \gamma \vec{j}_s(x, t) \times \vec{B}_s - \tau \frac{\partial \vec{j}_s(x, t)}{\partial t},$$

(7)

where

$$D = \frac{v_F^2}{3} \tau$$

(8)

is the diffusion constant and $\mu = e\tau/m^*$ the electron mobility. Note that $\vec{n}_s(x, t)$ and $\vec{j}_s(x, t)$ defined above are the particle (electron) number densities, which can be converted to the charge, spin, and magnetic moment densities by multiplication with $-e$, $\hbar/2$, and $-\mu_B$, respectively. The spin density $\vec{n}_s(x, t)$ can also be converted to the chemical potential difference $\mu_s(x, t)$, i.e., the spin accumulation, by the relation $\vec{n}_s(x, t) = \mathcal{N} \mu_s(x, t)$, where $\mathcal{N} = 4\pi m^2 v_F/\hbar^3$ is the density of states at the Fermi level of the electron gas for one spin orientation.

Equation (7) resembles the dynamical equation for the spin current derived by Qi and Zhang using a “mean field” approximation. Our derivation shows that their quantity $v_z^2$ is equal to $v_F^2/3$. As will be discussed in the next section, this is the wavefront velocity for a spin disturbance, which plays an important role in spin-signal propagation dynamics.

III. TELEGRAPH EQUATION

To see the physical significance of Eqs. (6) and (7) for the time-dependent noncollinear spin transport and compare them with the Bloch-Torrey equation, we combine them by
eliminating \( j_s(x, t) \) into a form reminiscent of a telegraph equation:\(^{21}\)
\[
\frac{\partial^2 \vec{n}_s(x, t)}{\partial t^2} + \left( \frac{1}{\tau} + \frac{1}{T_1} \right) \frac{\partial \vec{n}_s(x, t)}{\partial t} + \frac{\vec{n}_s(x, t)}{\tau T_1} + \gamma \left[ 2 \frac{\partial}{\partial t} + \left( \frac{1}{\tau} + \frac{1}{T_1} \right) \right] \vec{n}_s(x, t) \times \vec{B}_s \\
+ \gamma^2 [\vec{n}_s(x, t) \times \vec{B}_s] \times \vec{B}_s \\
= c_s^2 \frac{\partial^2 \vec{n}_s(x, t)}{\partial x^2} + \frac{\mu E(x, t)}{\tau} \frac{\partial \vec{n}_s(x, t)}{\partial x} + \frac{\mu \partial E(x, t)}{\tau} \vec{n}_s(x, t).
\]
(9)

Similarly, one can also derive a telegraph equation for \( j_s(x, t) \) by eliminating \( \vec{n}_s(x, t) \) from Eqs. (6) and (7). Equation (9) contains a second-order time derivative, which is absent in the spin diffusion equation. The second-order time and space derivatives lead to a wave character in addition to its diffusion character, and thus yield a well-defined propagation velocity \( c_s \) for the signal in time-dependent noncollinear spin transport in a similar way to the collinear case\(^{21}\).

Assuming the static magnetic field \( \vec{B}_s \) to be oriented along the z axis and separating the components perpendicular (transverse) and parallel (longitudinal) to \( \vec{B}_s \) in Eq. (9), we have
\[
\frac{\partial^2 n_s^{x(y)}(x, t)}{\partial t^2} + \left( \frac{1}{\tau} + \frac{1}{T_1} \right) \frac{\partial n_s^{x(y)}(x, t)}{\partial t} + \frac{n_s^{x(y)}(x, t)}{\tau T_1} + (-) \gamma B_s \left[ 2 \frac{\partial}{\partial t} + \left( \frac{1}{\tau} + \frac{1}{T_1} \right) \right] n_s^{y(x)}(x, t) \\
= c_s^2 \frac{\partial^2 n_s^{x(y)}(x, t)}{\partial x^2} + \frac{\mu E}{\tau} \frac{\partial n_s^{x(y)}(x, t)}{\partial x} + \frac{\mu \partial E}{\tau} n_s^{x(y)}(x, t).
\]
(10)

and
\[
\frac{\partial^2 n_s^z(x, t)}{\partial t^2} + \left( \frac{1}{\tau} + \frac{1}{T_1} \right) \frac{\partial n_s^z(x, t)}{\partial t} + \frac{n_s^z(x, t)}{\tau T_1} = c_s^2 \frac{\partial^2 n_s^z(x, t)}{\partial x^2} + \frac{\mu E}{\tau} \frac{\partial n_s^z(x, t)}{\partial x} + \frac{\mu \partial E}{\tau} n_s^z(x, t).
\]
(11)

In the following, only the equation for the transverse component [Eq. (10)] will be discussed, since the equation for the longitudinal component is similar to that of the collinear case\(^{21}\).

For vanishing electric field, i.e., \( E = 0 \), we seek damped and dispersive wave solutions to Eq. (10) of the form
\[
n_s^x(x, t) = n_0 \exp[i(kx - \omega t)],
\]
(12)
\[
n_s^y(x, t) = n_0 \exp[i(kx - \omega t + \phi)],
\]
(13)

where \( \omega \) is the angular frequency and \( k = k_r + ik_i \) the complex wave vector. Substituting Eqs. (12) and (13) into Eqs. (10), we obtain the dispersion relation
\[
\omega^2 + i\omega(1/\tau + 1/T_1) - 1/(\tau T_1) - c_s^2 k^2 + \gamma^2 B_s^2 - \gamma B_s [2\omega + i(1/\tau + 1/T_1)] \sin \phi = 0,
\]
(14)

where \( \phi \) is restricted to \( \phi = \pm(\pi/2) + 2n\pi \) and \( n \) is an integer, because \( n_s^x \) and \( n_s^y \) must satisfy the system of equations (10) at the same time. According to Eqs. (12) and (13),
\( \phi = +(-)\pi/2 \) corresponds to the rotation direction of the transverse component of \( \vec{n}_s(x, t) \) with \( x \) at time \( t \). For definiteness, we study the case with \( \phi = \pi/2 \) in the following. Substituting \( k = k_r + ik_i \) into Eq. (14) and separating the real and imaginary parts, we have

\[
k_r^2 = \frac{1}{2c_2^2} \left[ \sqrt{b^2 + \omega_{\text{eff}}^2 \alpha^2 + (-)b} \right], \tag{15}
\]

where \( \omega_{\text{eff}} = \omega - \gamma B_s \) and \( b = \omega_{\text{eff}}^2 - \xi \). Here, the constants \( \alpha = 1/\tau + 1/T_1 \) and \( \xi = 1/(\tau T_1) \) have been introduced. The wavelength and damping length can be defined as \( \lambda = 2\pi/k_r \) and \( l_d = 1/k_i \), respectively. The equation of the critical angular frequency \( \omega_{\text{crit}} \), above which the wave character is significant, can be derived by setting \( \lambda = l_d \),

\[
\omega_{\text{crit}} \tau = \frac{1}{2} \left[ \delta(1 + \eta) + \sqrt{\delta^2(1 + \eta)^2 + 4\eta} \right] \approx \delta + (\delta + \frac{1}{\delta})\eta, \tag{16}
\]

where \( \delta = \pi - 1/(4\pi) \approx 3.06 \) and \( \eta = \tau/T_1 \). Then, we have \( \omega_{\text{crit}} \tau = 3.06 + 3.47\eta + \tau\gamma B_s \) approximately.

**IV. DYNAMICS OF PUMPED SPIN CURRENT**

In this section, we study the evolution of the spin current injected into a nonmagnetic layer by the spin-pumping mechanism.\(^{15}\) In a junction composed of a ferromagnetic (\( x < 0 \)) and a nonmagnetic (\( x > 0 \)) layer, the magnetization precession of the ferromagnet around an external magnetic field \( \vec{B}_{\text{pump}} \) acts as a “spin pump” which transfers spin angular momentum from the ferromagnet to the adjacent nonmagnetic layer. The spin current density pumped into the nonmagnetic layer is\(^{15,29,30}\)

\[
\vec{j}_s^{\text{pump}} = \frac{1}{2\pi} \frac{g^{11}}{S} \vec{\hat{m}} \times \frac{d\vec{m}}{dt}, \tag{17}
\]

where \( g^{11} \) is the spin-mixing conductance and \( S \) the area of the interface. Here, \( \vec{m} \) is the unit vector for the magnetization of the ferromagnet. Note that the pumped spin current has been converted to a particle number current density \( \vec{j}_s^{\text{pump}} \). Since we are interested in the spin current pumped into a nonmagnetic layer and not in the dynamics of the ferromagnet, we neglect the back-flow spin current \( \vec{I}_s^{\text{back}} \), which flows from the nonmagnetic layer to the ferromagnet due to the spin accumulation in the nonmagnetic layer.\(^{29}\) Although the back-flow spin current can limit the achievable spin current into the nonmagnetic conductor, we do not approach this limit here. With this simplification, we have \( \vec{j}_s^{\text{pump}} = \vec{j}_s(x = 0, t) \),
where \( \vec{j}_s(x = 0, t) \) is the spin current density at the left boundary of the nonmagnetic layer. Separating the components perpendicular and parallel to the magnetic field \( \vec{B}_{\text{pump}} \), we can write \( \vec{j}_s(x = 0, t) \) as

\[
\begin{align*}
    j_x^s(x = 0, t) &= g^{\uparrow\downarrow}(4\pi S)^{-1}\omega\sin(2\theta)\cos(\omega t) \\
    j_y^s(x = 0, t) &= g^{\uparrow\downarrow}(4\pi S)^{-1}\omega\sin(2\theta)\sin(\omega t) \\
    j_z^s(x = 0, t) &= g^{\uparrow\downarrow}(2\pi S)^{-1}\omega\sin^2 \theta,
\end{align*}
\]

where \( \omega \) is the angular frequency of both the magnetization precession and the spin current density \( \vec{j}_s(x = 0, t) \). Here, \( \omega t \) is the angle between \( \vec{j}_s^\perp \) (\( j_x^s \) and \( j_y^s \)) and the \( x \)-axis. \( \theta \) is the angle between \( \vec{m} \) and \( \vec{B}_{\text{pump}} \), and meanwhile \( \theta \) is also the angle between \( \vec{j}_s(x = 0, t) \) and \( xy \)-plane. The amplitude of \( \vec{j}_s^\perp \) is much larger than \( j_z^s \), since \( \theta \) is very small under the usual radio-frequency excitation conditions. Therefore, we will focus on \( \vec{j}_s^\perp \) in the following.

The propagation of \( \vec{j}_s^\perp(x = 0, t) \) into the nonmagnetic layer is described by Eqs. (6) and (7). In a typical setup for spin pumping, there is no electric or magnetic field in the nonmagnetic layer, i.e., \( E = 0 \) and \( \vec{B}_s = 0 \). Now, separating the components perpendicular and parallel to the magnetic field \( \vec{B}_{\text{pump}} \), we can rewrite Eqs. (6) and (7) as

\[
\begin{align*}
    \frac{\partial n^+_s}{\partial t} + \frac{\partial j^+_s}{\partial x} &= -\frac{n^+_s}{T_1}, \\
    j^+_s &= -D \frac{\partial n^+_s}{\partial x} - \tau \frac{\partial j^+_s}{\partial t},
\end{align*}
\]

where \( n^+_s = n^x_s + in^y_s \) and \( j^+_s = j^x_s + ij^y_s \) are introduced to simplify the notations. The equations for the parallel component can be obtained after replacing \( n^+_s \) and \( j^+_s \) by \( n^z_s \) and \( j^z_s \) in Eqs. (21) and (22), respectively. The method of characteristics used for the numerical solution to Eqs. (21) and (22) is outlined in Appendix B.

In our numerical calculation, Cu and permalloy (Py) are chosen as the materials for the nonmagnetic and ferromagnetic layers, respectively. The Fermi velocity of Cu is \( v_F = 1570 \text{ nm/ps} \) and thus the wave-front velocity is \( c_s = v_F/\sqrt{3} = 906 \text{ nm/ps} \). The momentum and spin relaxation times are \( \tau = 0.07 \text{ ps} \) and \( T_1 = 3.5 \text{ ps} \), respectively. The critical frequency can be estimated to be \( \nu_{\text{crit}} = \omega_{\text{crit}}/(2\pi) = 7.11 \text{ THz} \) from Eq. (16). We study several pumping frequencies: \( \nu_a = 1/T_a = 2 \text{ GHz} \), \( \nu_b = 1/T_b = 20 \text{ GHz} \), \( \nu_c = 1/T_c = 200 \text{ GHz} \), and \( \nu_d = 1/T_d = 8.33 \text{ THz} \). For a Py/Cu junction, \( g^{\uparrow\downarrow} \approx 10^{15} \text{ cm}^{-2} \). The precession cone angle \( \theta \) can reach 15° for a sufficiently intense radio-frequency field.
FIG. 1: Snapshots of the spin current density $\vec{j}_s^\perp$ at $t = 5/4 \ T_a$, $5/4 \ T_b$, and $5/4 \ T_c$, for the frequencies, $\nu_a$, $\nu_b$, and $\nu_c$, respectively (see text). $\vec{j}_s^\perp$ is plotted as vector starting from its $x$-coordinate.

Therefore, we choose the amplitude of $\vec{j}_s^\perp$, i.e., $g^{1\downarrow}(4\pi S)^{-1}\omega \sin(2\theta)$, to be $5 \times 10^{-3}$ nm$^{-2}$ ps$^{-1}$ for the frequencies mentioned above.

Figure 1 shows snapshots of the spin current density $\vec{j}_s^\perp$ at $t = 5/4 \ T_a$, $5/4 \ T_b$, and $5/4 \ T_c$, for the frequencies, $\nu_a$, $\nu_b$, and $\nu_c$, respectively. According to Eqs. (18), $\vec{j}_s^\perp(x = 0, t)$ points in the direction of the $y$-axis at $t = 5/4 \ T_a(b,c)$, which can also be seen in Fig. 1. Figure (a) shows that $\vec{j}_s^\perp$ points along $y$-axis nearly at all $x$ points except that it deviates from the $y$-axis slightly at positions far away from $x = 0$. The results in Fig. (a) are approximately consistent with those obtained from the diffusion equation in Refs. 29 and 30, where it is shown that both the spin current and spin accumulation point along the same direction at all positions for all frequencies at certain time point $t$. This agreement means that the diffusion equation provides a good description in the low frequency range. The deviation of $\vec{j}_s^\perp$ from the $y$-axis at $x > 0$ increases with frequency and becomes noticeable at $\nu_b = 1/T_b = 20$ GHz as shown in Fig. (b). Therefore, the applicability of the diffusion equation is questionable in this frequency region. At even higher frequency, $\nu_c = 1/T_c = 200$ GHz, the deviation becomes significant and the diffusion equation is not applicable.
Moreover, the damping length of $\vec{j}_s^\perp$ decreases with frequency due to the ‘skin’ effect. We can conclude that the spin diffusion equation is applicable only in the low frequency range and amounts to an adiabatic approximation: the external perturbation is assumed to be much slower than the internal dynamics of the electronic system.

Figure 2 shows snapshots of the spin density $\vec{n}_s^\perp$ for the same parameters as in Fig. 1. The spin density $\vec{n}_s^\perp$ deviates from $y$-axis at $x = 0$ and is noncollinear with $\vec{j}_s^\perp$ at $x > 0$ at all of the three frequencies. This feature is different from the result of the diffusion equation, where $\vec{j}_s^\perp$ and $\vec{n}_s^\perp$ are collinear. The phase shift and the amplitude of $\vec{n}_s^\perp$ also vary with frequency. Moreover, the damping length of $\vec{n}_s^\perp$ decreases with frequency again due to the ‘skin’ effect.

According to Eq. (16), the diffusion character is dominant at the frequencies considered so far, because they are still much smaller than the critical frequency $\nu_{\text{crit}}$. This conclusion is supported by the numerical results presented in Figs. 1 and 2, although Figs. 1 (c) and 2 (c) have already shown weak wavelike character. The deviation from the diffusion equation depends largely on the frequency of the spin signal and momentum relaxation time, which varies with material, temperature, doping and excitation condition. In the following, we show the numerical results for a frequency $\nu_d = 8.33$ THz, where the wave character is significant according to Eq. (16).
FIG. 3: Snapshots of $\vec{j}_s^\perp$ at $t = T_d$, $2T_d$, and $3T_d$, where $T_d = 0.12$ ps. The solid (dashed) curve is for $j_s^x (j_s^y)$.

Figure 3 shows snapshots of the spin current density $\vec{j}_s^\perp$ at $t = T_d$, $2T_d$, and $3T_d$, respectively. The wave form and wave front are clearly visible in Fig. 3. The propagation velocity of the spin signal can be estimated by tracking the motion of the wave front. The result is approximately equal to the analytical result $c_s = 906$ nm/ps. The phase velocity can also be estimated by measuring the wavelength $\lambda$ and using $v_p = \lambda/T_d$. The result is roughly equal to the wave front velocity $c_s$, which also indicates the significance of the wave character, albeit on the length scale of the damping length (dynamical spin diffusion length). To demonstrate the wave character more directly, we plot the results of Fig. 3 (a) again in Fig. 4 where $\vec{j}_s^\perp$ is shown in a vector plot. Note that $\nu_d$ is beyond the frequency range in which Eq. (17) is valid, because Eq. (17) is only applicable in the adiabatic limit, $\nu \ll 1/\tau$. Unfortunately, there is no corresponding theoretical result for the nonadiabatic spin-pumping in the literature. However, it is a reasonable guess that the pumped spin current density in the nonadiabatic regime preserves the basic feature of Eq. (17): $\vec{j}_s^{\text{pump}}$ rotates with a certain fixed frequency. Therefore, the spin current predicted by our results should be at least qualitatively accurate in this frequency range.
V. SUMMARY

We showed that time-dependent noncollinear spin transport exhibits a wave character for modulation of the spin current on timescales shorter than an inverse critical frequency. A finite propagation velocity for the spin signal can be defined due to this wave character. The spin diffusion equation is recovered only for modulation with frequencies less than the critical frequency, and amounts to an adiabatic approximation of time-dependent spin transport.

APPENDIX A: DERIVATION

Equations (6) and (7) of Ref. 27 are derived using the “mean field” approximation

$$\sum_{\vec{v}} v_x^2 \left( \partial \rho / \partial x \right) \approx \overline{v_x^2} \sum_{\vec{v}} \left( \partial \rho / \partial x \right).$$

(A1)

Here we show that $\overline{v_x^2} = c_s^2$ by evaluating the sums occurring in Eq. (A1). We start with the LHS, which we denote by $I_1 = \sum_{\vec{v}} v_x^2 \left( \partial \rho / \partial x \right)$. Due to the cylindrical symmetry of the system around the $x$ axis in velocity space, $\dot{\rho}$ can be expanded in Legendre polynomials of $u = \cos \theta$, where $\theta$ is the angle between $\vec{v}$ and the $x$ axis, as

$$\dot{\rho} = \sum_{n=0}^{\infty} \hat{\rho}_n(v, x) P_n(u).$$

(A2)
Transforming the summation into an integral, we have

$$I_1 = \frac{2\pi V m^3}{h^3} \int_{-1}^{1} du u^2 \int_0^\infty dv v^4 \sum_{n=0}^{\infty} \frac{\partial}{\partial x} \hat{\rho}_n(v, x) P_n(u).$$  (A3)

Using $u^2 = [2P_2(u) + P_0(u)]/3$, we write the integral as

$$I_1 = \frac{2\pi V m^3}{h^3} \int_0^\infty dv v^4 \sum_{n=0}^{\infty} \frac{\partial}{\partial x} \hat{\rho}_n(v, x) \int_{-1}^{1} du \frac{1}{3} [2P_2(u) + P_0(u)] P_n(u).$$  (A4)

Making use of the orthogonality relation of Legendre polynomials, we have

$$I_1 = \frac{2\pi V m^3}{h^3} \int_0^\infty dv v^4 \frac{\partial}{\partial x} \left[ \frac{4}{15} \hat{\rho}_2(v, x) + \frac{2}{3} \hat{\rho}_0(v, x) \right].$$  (A5)

If the system is weakly anisotropic, we can neglect the second-order term $\hat{\rho}_2(v, x)$,

$$I_1 \approx \frac{4\pi V m^3}{3h^3} \int_0^\infty dv v^4 \frac{\partial}{\partial x} \hat{\rho}_0(v, x).$$  (A6)

This approximation is consistent with Ref. 4, where the second-order term of the Legendre polynomials is neglected and it is shown that this is valid if $\sqrt{\tau/(2T_1)} \ll 1$.

Because $\partial \hat{\rho}_0(v, x)/\partial x$ is zero unless $v$ falls in a small region $[v_F - \Delta v, v_F + \Delta v]$ around the Fermi velocity $v_F$ of a system with a degenerate electron gas, we have approximately

$$I_1 = \frac{4\pi V m^3}{h^3} \frac{v_F^2}{3} \int_{v_F - \Delta v}^{v_F + \Delta v} dv v^2 \frac{\partial}{\partial x} \hat{\rho}_0(v, x) = \frac{v_F^2}{3} \frac{4\pi V m^3}{h^3} \int_0^\infty dv v^2 \frac{\partial}{\partial x} \hat{\rho}_0(v, x).$$  (A7)

We now need to evaluate the RHS of Eq. (A1), which we denote by

$$I_2 = v_x^2 \frac{V m^3}{h^3} 2\pi \int_{-1}^{1} du \int_0^\infty dv v^2 \frac{\partial}{\partial x} \hat{\rho}(v, x) = v_x^2 \frac{4\pi V m^3}{h^3} \int_0^\infty dv v^2 \frac{\partial}{\partial x} \hat{\rho}(v, x).$$  (A8)

where, in the last line, we used that the integral over $u$ projects the contribution of $P_0$ out of $\hat{\rho}(v, x)$. Because $I_1 = I_2$, we conclude that $v_x^2 = v_F^2/3 \equiv c_s^2$.

**APPENDIX B: NUMERICAL SOLUTION**

The basics of our numerical method have been outlined in Appendix A4 of Ref. 21. For present calculation, it has to be augmented by a discretized version of the boundary condition on at ferromagnet/nonmagnet interface,

$$(\Delta t/T_1 + 2) n_{s,i}^{t+1} = - (\Delta t/T_1 - 2) n_{s,i+1}^{t} + c_s^{-1} (\Delta t/\tau - 2) j_{s,i+1}^{t+1} + c_s^{-1} (\Delta t/\tau + 2) j_{s,i}^{t+1}$$  (B1)
where the subscripts $i$ and superscripts $l$ stand for the discrete space-time points, and $\Delta t$ is the numerical time step.
