**Abstract:** *Clostridioides difficile* has been recognized as a life-threatening pathogen that causes enteric diseases, including antibiotic-associated diarrhea and pseudomembranous colitis. The severity of *C. difficile* infection (CDI) correlates with toxin production and antibiotic resistance of *C. difficile*. In Thailand, the data addressing ribotypes, toxicogenic, and antimicrobial susceptibility profiles of this pathogen are scarce and some of these data sets are limited. In this study, two groups of *C. difficile* isolates in Thailand, including 50 isolates collected from 2006 to 2009 (THA group) and 26 isolates collected from 2010 to 2012 (THB group), were compared for toxin genes and ribotyping profiles. The production of toxins A and B were determined on the basis of toxin gene profiles. In addition, minimum inhibitory concentration of eight antibiotics were examined for all 76 *C. difficile* isolates. The isolates of the THA group were categorized into 27 A−B∗CDT− (54%) and 23 A B∗CDT− (46%), while the THB isolates were classified into five toxicogenic profiles, including six A∗B∗CDT+ (23%), two A B∗CDT− (8%), five A−B∗CDT+ (19%), seven A−B∗CDT− (27%), and six A B−CDT− (23%). By visually comparing them to the references, only five ribotypes were identified among THA isolates, while 15 ribotypes were identified within THB isolates. Ribotype 017 was the most common in both groups. Interestingly, 18 unknown ribotyping patterns were identified. Among eight tcdA-positive isolates, three isolates showed significantly greater levels of toxin A than the reference strain. The levels of toxin B in 3 of 47 tcdB-positive isolates were significantly higher than that of the reference strain. Based on the antimicrobial susceptibility test, metronidazole showed potent efficiency against most isolates in both groups. However, high MIC values of cefoxitin (MICs ≥ 256 µg/mL) and chloramphenicol (MICs ≥ 64 µg/mL) were observed with most of the isolates. The other five antibiotics exhibited diverse MIC values among two groups of isolates. This work provides evidence of temporal changes in both *C. difficile* strains and patterns of antimicrobial resistance in Thailand.

**Keywords:** *C. difficile* infection; molecular analysis; toxin production; antibiotic resistance

1. *Introduction*

*Clostridioides difficile* (formerly *Clostridium difficile*), belonging to the family *Clostridiaceae* and genus *Clostridioides*, is an obligate anaerobic, Gram-positive, spore-forming, toxin-producing bacillus [1,2]. This organism is well known to cause infectious diarrhea in humans, ranging from mild diarrhea to severe pseudomembranous colitis [3]. *C. difficile*
infection (CDI) has been primarily a healthcare-associated illness, which can occur during antibiotic treatment. Furthermore, the ability of *C. difficile* to form spores leads to the problem of recurring infection. The persistence of spores in the physical environment facilitates its transmission [4]. The pathogenesis of CDI is attributed to the production of two major toxins: toxins A and B. Toxin A is an enterotoxin encoded by *tcdA*, and toxin B is a cytotoxin encoded by *tcdB*. Both toxins belong to the family of large clostridial toxins (LCTs) and are located within a 19.6 kb pathogenicity locus (PaLoc) [5]. In addition to toxins A and B, some strains of *C. difficile* also produce a binary toxin (CDT) encoded by two genes, *cdtA* and *cdtB*, on CdtLoc, a separate pathogenicity island [6]. Although CDTs are not directly required for diseases, they have been known to promote the virulence of *C. difficile* by impairing host immunity and acting in synergy with toxins A and B, exacerbating toxicity [7].

Over the recent decades, the epidemiology of CDI has dramatically changed. The epidemiology in North America and Europe and some parts of Asia is well-documented. While ribotype 027 causes major outbreaks in North America and Europe, ribotype 017 is the most dominant ribotype in Asia [8,9]. In Thailand, *tcdA*-negative, *tcdB*-positive ribotype 017 is the most prevalent *C. difficile* strain [10–12]. However, the occurrence of *C. difficile* has increased and influenced the incidence of CDI in many areas. Several ribotypes have emerged and lead to epidemic infections across the world; for example, ribotype 014/20 in Australia [13,14], ribotype 369 in Japan [15], and ribotype 078 in China [16].

Antibiotic use plays a major role in the development of CDI and recurrent diseases by disrupting the normal flora in the gut and allowing the invasion of *C. difficile* [17,18]. The first-line treatment for CDI is the use of antibiotics, including vancomycin, fidaxomicin, and metronidazole [19,20]. However, drug resistance has become one contributing factor that drives the global prevalence of CDI [21–24]. Although information on *C. difficile* has been globally expanded, little knowledge of antibiotic susceptibility of *C. difficile* in Thailand is available. Previous studies showed that *C. difficile* isolates in Thailand were susceptible to vancomycin and metronidazole. However, a high resistance level against multiple antibiotics, such as clindamycin, erythromycin, and moxifloxacin has been reported [25,26]. This study was conducted to compare two groups of *C. difficile* clinical isolates collected in different time periods from a University-affiliated tertiary hospital and the National Institute of Health of Thailand. To describe the diversity of *C. difficile* clinical isolates during 2006–2009 and 2010–2012, the presence of toxin genes and ribotype, including toxin levels and antimicrobial susceptibility patterns, were characterized using molecular techniques.

2. Results

2.1. Toxin Gene Profiles of *C. difficile* Isolates

The multiplex PCR was employed to identify the toxin gene profiles of *C. difficile* isolates. Seventy-six *C. difficile* isolates were classified into five profiles based on the presence of toxin genes. Only two toxigenic types were observed in the THA group. Twenty-seven THA isolates (54%) were characterized as *A−B+CDT−* (toxigenic), and 23 THA isolates (46%) were *A−B−CDT−* (non-toxigenic) (Figure 1A). All 27 isolates in the THA group that were previously positive for *tcdA* carried the *tcdA* 3′-end deletion (Supplementary Table S1). Later, they were grouped as *tcdA*-negative isolates instead. Thus, none of the toxigenic isolates in the THA group were *tcdA*-positive. In the THB group, six isolates (23%) were classified as *A+B+CDT+*, five isolates (19%) as *A−B+CDT−*, two isolates (8%) as *A+B−CDT−*, seven isolates (27%) as *A−B−CDT−*, and six isolates (23%) as *A−B−CDT+* (Figure 1B). Among *tcdA*-negative isolates in the THB group, in 12 isolates (63%) were found the deletion regions within the 3′-end (Table S1). Based on the molecular analysis, around 54% of the THA isolates and 77% of the THB isolates were toxigenic (Figure 1). The most dominant toxigenic type was *A−B+*, which was about 54% of THA isolates and 46% of THB isolates.
THA isolates and 77% of the THB isolates were toxigenic (Figure 1). The most dominant toxigenic type was $A^{-}B^{+}$, which was about 54% of THA isolates and 46% of THB isolates.

Figure 1. Toxin gene analysis of C. difficile isolates. The distribution of toxin profiles in C. difficile isolates from (A) THA group, which contained C. difficile isolates collected from 2006 to 2009 (n = 50) and (B) THB group, which contained C. difficile isolates collected from 2010 to 2012 (n = 26). Toxin profiles were characterized based on the presence of toxin genes and the deletion of tcdA 3′-end. A, B, and CDT represent tcdA, tcdB, and cdtAB.

2.2. Ribotypes of C. difficile Isolates

The band patterns of 16S and 23S rRNA PCR products were compared to the reference C. difficile ribotypes (Figure S1). Based on PCR ribotyping, THA isolates were separated into five ribotypes (Figure 2A). Ribotype 017 was the only standard ribotype found in the THA group, whereas the other four ribotypes showed different patterns from the standards (NN or NT). The dominant ribotype was NN05, followed by ribotype 017 and NN07. Even though the number of isolates in the THB group was lower compared to the THA group, THB isolates were classified into 15 ribotypes (Figure 2B). Ribotype 017 had the highest prevalence in the THB group with seven isolates (27%). Only one isolate (4%) was classified as ribotype 020. Alternatively, the other 14 isolates in the THB group showing distinct ribotyping patterns compared to the references were classified into 13 unknown ribotypes. The distribution of toxin gene profiles and ribotyping profiles is elaborated in Table 1. Diverse ribotypes were observed with each toxin gene profile; for instance, the $A^{+}B^{+}CDT^{+}$ group was composed of five ribotyping patterns, RT020, NT01, NT03, NT05, and NT06 (Table 1). These results suggest a high diversity of C. difficile isolates in Thailand.
THA isolates and 77% of the THB isolates were toxigenic (Figure 1). The most dominant toxigenic type was $A^{-}B^{+}+CDT$, which was about 54% of THA isolates and 46% of THB isolates.

Figure 1. Toxin gene analysis of C. difficile isolates. The distribution of toxin profiles in C. difficile isolates from (A) THA group, which contained C. difficile isolates collected from 2006 to 2009 ($n = 50$) and (B) THB group, which contained C. difficile isolates collected from 2010 to 2012 ($n = 26$). Toxin profiles were characterized based on the presence of toxin genes and the deletion of tcdA 3′-end. A, B, and CDT represent tcdA, tcdB, and cdtAB.

2.2. Ribotypes of C. difficile Isolates

The band patterns of 16S and 23S rRNA PCR products were compared to the reference C. difficile ribotypes (Figure S1). Based on PCR ribotyping, THA isolates were separated into five ribotypes (Figure 2A). Ribotype 017 was the only standard ribotype found in the THA group, whereas the other four ribotypes showed different patterns from the standards (NN or NT).

The dominant ribotype was NN05, followed by ribotype 017 and NN07. Even though the number of isolates in the THB group was lower compared to the THA group, THB isolates were classified into 15 ribotypes (Figure 2B). Ribotype 017 had the highest prevalence in the THB group with seven isolates (27%). Only one isolate (4%) was classified as ribotype 020. Alternatively, the other 14 isolates in the THB group showing distinct ribotyping patterns compared to the references were classified into 13 unknown ribotypes.

Table 1. Summary of toxin gene profiles and ribotyping profiles of 76 C. difficile isolates in Thailand.

| Toxigenic Profile | No. of Isolates | THA (n = 50) | THB (n = 26) | RT017 | RT020 | NN01 | NN02 | NN03 | NN04 | NN05 | NN06 | NN07 | NT01 | NT02 | NT03 | NT04 | NT05 | NT06 | NT07 | NT08 | NT09 | NT10 | NT11 |
|-------------------|----------------|-------------|-------------|-------|-------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|
| A^{-}B^{+}+CDT    | 6              | 1           |             |       |       |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |
| A^{-}B^{+}+CDT    | 2              |             |             |       |       |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |
| A^{-}B^{+}+CDT    | 5              | 1           |             |       |       |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |
| A^{-}B^{+}+CDT    | 27             | 7           | 20          |       |       |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |
| A^{-}B^{+}+CDT    | 6              | 3           | 1           | 1     | 1     |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |
| A^{-}B^{+}+CDT    | 3              | 6           |             |       |       |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |

These results suggest a high diversity of C. difficile isolates in Thailand.

Figure 2. Ribotypes of C. difficile isolates using PCR ribotyping method. (A) The distribution of ribotypes among C. difficile isolates in the THA group ($n = 50$). (B) The distribution of ribotypes among C. difficile isolates in the THB group ($n = 26$). PCR ribotyping was performed on 16S and 23S rRNA genes. Ribotypes were assigned based on the band patterns of gel electrophoresis. RT017 and RT020 represent the standard C. difficile ribotypes. NT and NN represent new ribotype patterns of C. difficile toxigenic and non-toxigenic isolates, respectively.
2.3. Toxin Production of C. difficile Isolates

Toxin production of C. difficile is a significant factor causing CDI [27]. In this study, toxin production of toxigenic C. difficile isolates, including \( A^+B^+ \), \( A^+B^- \), and \( A^-B^+ \), was accessed using indirect ELISA. The toxin levels of individual isolates were compared to the toxin production of C. difficile R20291 (\( A^+B^+CDT^+ \)), a recent emergence of a highly virulent bacterium. The unique ability of hypervirulent strain R20291 is associated with an increase in toxin production [28]. The amounts of toxins A and B were similar among toxigenic isolates in the THA and THB groups. Notably, four toxin-positive isolates, THB1, THB38, THB156, and THB376, significantly increased toxin A levels (2–9 folds) compared to R20291 (Figure 3A). Toxigenic THA isolates were found to produce similar levels of toxin B to the reference strain. Three isolates, THB2, THB136, and THB156, significantly produced greater levels of toxin B (3–6 folds) compared to the reference strain (Figure 3B). Interestingly, THB156 was the only toxigenic isolate that produced a significantly high level of toxin A and B. On the basis of these results, many THB isolates represented high toxin producers, suggesting increased toxin production of toxigenic C. difficile isolates in Thailand.

![Figure 3. The relative level of toxin A and B production of C. difficile isolates. Toxigenic C. difficile isolates in the THA group; \( B^+ \) (n = 27) and the THB group; \( A^+ \) (n = 8) and \( B^+ \) (n = 20) were subjected to indirect ELISA. (A) The light blue bars represent toxin A, and (B) the dark blue bars represent toxin B. The graph shows average values of 3 independent samples in the experiments. Error bars refer to mean ± SEM, \( p < 0.05 \), *, and \( p < 0.01 \), **.](image-url)

2.4. Antimicrobial Resistance Profiles of C. difficile Isolates

Antibiotic resistance has become one of the major challenges of CDI treatment. In this study, the antimicrobial susceptibility of the 76 C. difficile isolates was determined using the minimum inhibitory concentration (MIC) method. A variety of MIC values of eight antibiotics were observed across C. difficile isolates (Figure 4). Antibiotic susceptibility patterns of two groups of isolates are summarized in Table 2. In the THA group, 48 isolates (96%) were susceptible to amoxicillin with an MIC\(_{90}\) of 2 \( \mu g/mL \), while 46 isolates (92%) were susceptible to ampicillin with an MIC\(_{90}\) of 4 \( \mu g/mL \). All THA isolates were resistant to chloramphenicol with an MIC\(_{90}\) of \( \geq 64 \mu g/mL \). In addition, all THA isolates were resistant to cefoxitin, except one isolate with an MIC\(_{90}\) of 256 \( \mu g/mL \). Conversely, all isolates in the THA group were susceptible to metronidazole with an MIC\(_{90}\) of 4 \( \mu g/mL \). Amoxicillin and ampicillin showed potent activity against all THB isolates with an MIC\(_{90}\) of 2 and 4 \( \mu g/mL \), respectively. Additionally, most THB isolates were resistant to chloramphenicol with an MIC\(_{90}\) of \( \geq 64 \mu g/mL \) (96.15%), followed by cefoxitin with an MIC\(_{90}\) of 256 \( \mu g/mL \) (92.31%). None of the isolates in the THB group were resistant to metronidazole and only three THB isolates (11.54%) were resistance to vancomycin. In addition, three (11.54%) and two (7.69%) of THB isolates were resistant to levofloxacin and rifampicin, respec-
tively. Minor differences in the MIC range between THA and THB isolates were observed (Table 3). For instance, chloramphenicol showed an MIC range of 32- ≥ 64 µg/mL in THA isolates, and 16- ≥ 64 µg/mL in THB isolates. A slightly greater ratio of resistant isolates was shown in THA isolates compared to THB isolates. Overall, two groups of isolates showed similar patterns of MIC values. Most THA and THB isolates were susceptible to all antibiotics, except cefoxitin and chloramphenicol, which showed the highest MIC ranges and resistance rates (Table 2). In total, 49 (98%) of the THA isolates and 23 (88.46%) of the THB isolates were resistant to more than one antibiotic. Most of them were resistant to chloramphenicol, cefoxitin, and levofloxacin, which belong to different antibiotic classes. These findings demonstrated multidrug-resistant (MDR) strains among Thai C. difficile isolates (Table S2).

**Figure 4.** The MIC values of C. difficile isolates in Thailand. Eight antibiotics were used to investigate MIC values of C. difficile isolates in THA group (n = 50) and THB group (n = 26) using broth dilution method. The colors represent different MIC values.
### Table 2. Antibiotic susceptibility patterns of *C. difficile* isolates in Thailand.

| Antibiotics     | MIC Range (µg/mL) | MIC₅₀ (µg/mL) | MIC₉₀ (µg/mL) | Breakpoints (µg/mL) | Susceptible (%) | Intermediate (%) | Resistant (%) |
|-----------------|-------------------|---------------|---------------|---------------------|----------------|-----------------|--------------|
|                 | THA (n = 50)      | THB (n = 26)  | THA           | THB                 | THA            | THB             | THA          | THB          |
| Amoxicillin     | ≤0.125-32         | ≤0.125-0.5    | 0.5           | ≤0.125              | 2              | 0.5             | 96           | 100          | 2           | 0           | 0           |
| Ampicillin      | 0.25-16           | 0.25-4        | 2             | 2                   | 4              | 2               | 92           | 100          | 4           | 0           | 4           |
| Cefoxitin       | 4-256             | 4-256         | 256           | 256                 | 256            | 256             | 2            | 7.69         | 0           | 0           | 98          | 92.31       |
| Chloramphenicol | ≥32-64            | ≥16-64        | ≥64           | ≥64                 | ≥64            | ≥4             | 2            | 7.69         | 0           | 0           | 3.85        | 100         | 96.15       |

3. Discussion

C. difficile infection (CDI) has occurred worldwide over recent decades. The prevalence and epidemiology of C. difficile in many regions are well documented [31,32]. However, information on C. difficile occurrences in Thailand remains limited. This work was conducted to continuously update information on C. difficile clinical isolates in Thailand by comparing two groups of clinical isolates that were collected in different time periods. C. difficile isolates were classified based on molecular features, including toxin genes and the 16S–23S rRNA intergenic spacer regions [33,34]. Normally, three major toxigenic types (A+ B+, A− B−, A− B+) cause clinical incidences of CDI. The toxigenic type A+ B+ is the most common among toxigenic types [35,36]. However, the presence of tcdA 3′-end deletion has been detected in many clinical isolates, resulting in toxin A-negative C. difficile isolates [37,38]. About half of C. difficile isolates collected during 2006–2009 (THA group) were toxigenic with the highest occurrence of A+ B+ isolates (Figure 1A). Although isolates used in this study were obtained from the patients with CDI, consistent with previous studies, non-toxigenic strains were highly detected from clinical samples due to the mix of both the non-toxigenic and toxigenic populations and isolation method [10,39,40]. The population sizes of non-toxigenic and toxigenic C. difficile isolates in Thailand during 2006–2018 were comparable. The most dominant toxigenic isolates were tcdA-negative and tcdB-positive (A− B+) [10]. In contrast, the majority of C. difficile isolates collected during 2010–2012 (THB group) were toxigenic, and toxin gene profiles increased to five types, A−B−CDT−, A−B+CDT−, A+B+CDT−, A−B+CDT+, and A+B+CDT+ (Figure 1B). However, no A−B−CDT+ was detected in this study, corresponding to the previous study showing low prevalence of binary toxin-positive but toxin A- and B-negative C. difficile strains in France [41]. Some C. difficile isolates have the binary toxin gene (CDT), an actin-specific ADP-ribosyl transferase encoded by two genes, cdtA and cdtB on the CDT locus (Cdt-Loc) [6,42]. The binary toxins are widely observed in hypervirulent C. difficile, such as the ribotypes 027 and 078, which cause higher severity of CDI [43,44]. Therefore, the binary toxin may serve as an additional virulent factor by enhancing the production of toxins A and B. Our findings indicate a higher prevalence of toxigenic isolates in Thailand from 2010 to 2012.

Currently, PCR ribotyping is a general technique for epidemiological distinction of C. difficile isolates. This method amplifies polymorphic sequences between 16S and 23S intergenic spacer regions, which vary among strains [33,45,46]. It is the most common method employed for molecular analysis of C. difficile strains and is considered the gold standard method for C. difficile typing [10,11,33,47]. A similar incidence shown in the analysis of toxin genes was also observed with the ribotyping profiles. The number of ribotypes found during 2010–2012 was up to 16 ribotypes, from five ribotypes identified during 2006–2009 (Figure 2). C. difficile ribotype 017 has been recognized as a major cause of CDI outbreaks in Asia, and ribotype 020 is also a common strain [12,48]. Ribotype 017 was also the most frequently found in Thailand [11]. Consistent with this study, the most common ribotype in both groups was ribotypes 017. Besides, there were unknown ribotypes which showed different amplified patterns compared to the references between the two groups. However, we could not compare the PCR ribotyping patterns of the unknown ribotypes to other unknown ribotypes discovered in the previous studies in Thailand due to the limitation of this method. Other techniques, including pulse-field gel electrophoresis (PFGE), restriction endonuclease analysis (REA), and multilocus variable-number tandem-repeat analysis (MLVA), can be applied to improve typing of C. difficile strains [49,50]. Based on PCR ribotyping, molecular epidemiology of C. difficile isolated in Thailand significantly differs from other regions where ribotypes 027, 014/20, 002, 106, and 001 have dominated in North America and ribotypes 027, 014, 001, and 078 have frequently been isolated in Europe [51,52]. On the basis of toxin genes and ribotype identification, the diversity of C. difficile isolates in Thailand has increased over time.

Toxins A and B are the primary virulence factors contributing to the pathogenesis of CDI. They are considered to cause severe diseases [53]. Several studies have revealed
A high toxin production is one of the features of hypervirulent strains associated with the development of CDI. The expansion of strain diversity advocates antibiotic resistance in C. difficile [24,61,62]. To determine the direction of the antibiotic susceptibility of Thai C. difficile isolates, two groups of isolates were tested against several classes of antibiotics, which are recommended in infectious diarrhea [63,64]. None of the isolates fully resisted metronidazole, but three isolates showed intermediate resistance. However, 9 of 76 isolates had full resistance to vancomycin. This incidence was also observed in several studies with reduced susceptibility to vancomycin [22,65]. Our observations suggest a high efficiency of metronidazole for treating CDI, that also relates to the previous studies in Thailand [25,26]. Beta-lactam groups of antibiotics are most frequently correlated with CDI [66]. Several studies reported a low level of resistance to this antibiotic group [61,62]. In this study, amoxicillin and ampicillin also showed potent action against C. difficile isolates in Thailand. This supported the fact that antibiotics in the same class provide equal efficacy. Nevertheless, fluoroquinolones (ciprofloxacin, levofloxacin, moxifloxacin, norfloxacin) and cephalosporins (cefazolin, cephalaxin, ceftriaxone, cefotaxime, cefotetan, cefoxitin) are common antibiotic groups used for treating bacterial infection in the clinical setting, and they continue to promote CDI [67,68]. The same incidence was detected in this study, in which the majority of C. difficile isolates were resistant to levofloxacin and cefoxitin. Resistance to chloramphenicol is rare in C. difficile. Only a small number of isolates have been reported to be chloramphenicol resistant [24,69]. Contrary to our observations, all isolates fully resisted chloramphenicol, except for one that showed intermediate resistance. In addition, the reduced susceptibility to rifampicin in C. difficile clinical strains has been reported in Asia, Europe, and North America [69–71]. Correspondingly, rifampicin-resistant isolates were detected in the current study. On the basis of antibiotic resistance analysis, most C. difficile isolates in this study were resistant to multiple antibiotics, increasing the chance of treatment failure. Although C. difficile isolates between two periods showed distinct diversity, the difference in the patterns of antibiotic resistance was not observed in this study.

In summary, C. difficile isolates from patients diagnosed with diarrhea during 2006–2009 and 2010–2012 were characterized for toxigenic types, ribotypes, toxin production, and antibiotic resistance. The toxigenic profiles found in Thailand rose to five types, including $A^−B^+CDT^−$, $A^+B^+CDT^+$, $A^+B^+CDT^−$, $A^−B^+CDT^+$, and $A^−B^−CDT^−$. In particular, ribotype 017 was predominant among clinical isolates in Thailand. Additionally, 18 unknown ribotypes were discovered in Thai isolates. Some C. difficile isolates in Thailand were able to produce similar levels of toxins A and B to the toxins of the hypervirulent C. difficile strain, R20291. There was no difference in susceptibility to vancomycin and metronidazole between two periods, supporting the fact that they are primary antibiotics for CDI therapy. In addition, amoxicillin, ampicillin, and rifampicin also had an effective impact on treating isolates in Thailand. Based on these findings, this study presents temporal changes in C. difficile.
difficile strain diversity and patterns of antimicrobial resistance in Thailand, which will be useful for surveillance.

4. Materials and Methods

4.1. Sample Collection and Bacterial Culture

In total, 76 C. difficile clinical isolates were obtained from a University-affiliated tertiary hospital and the National Institute of Health of Thailand. The isolation of C. difficile from stool samples of diarrheal patients was performed in previous studies [39,40]. These isolates were separated into 2 groups based on collection periods. The THA group was composed of 50 isolates collected from 2006 to 2009, and the THB group contained 26 isolates collected from 2010 to 2012. Each isolate was cultured on cycloserine-cefoxitin fructose agar (CCFA) for 24 h at 37 °C under anaerobic conditions (Coy Laboratory Products, Glass Lake, MI, USA) supplemented with 0.1% taurocholate to recover and enrich C. difficile cells. A single colony was cultured in fresh brain heart infusion (BHI) broth and incubated in an anaerobic chamber at 37 °C for 24–48 h. The culture was preserved with 10% (v/v) glycerol at −80 °C for further use.

4.2. Toxin Genotyping

Genomic DNA of C. difficile isolates was extracted from BHI culture using an E.Z.N.A.® Stool DNA kit (Omega Bio-tek, Norcross, GA, USA), according to the manufacturer’s instructions. DNA purity and concentration were assessed by NanoDrop™ spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA). Toxigenic profiles of all C. difficile isolates were analyzed by multiplex PCR with 5 specific primer pairs, tcdA, tcdB, cdtA, cdtB, and 16S rDNA (Table 3). The PCR reaction was conducted in a total volume of 20 µL containing 25–200 ng of genomic DNA, 0.8 mM dNTPs, 5 mM MgCl₂, 1 × PCR buffer, (500 mM KCl, 100 mM tris-HCl, pH 9.1), 1U Taq DNA polymerase (Vivantis, kuala Lumpur, Malaysia), and 0.2 µM primers. Amplification was performed under a thermal cycler with cycling conditions including a predenaturation at 92 °C for 5 min, 30 cycles of denaturation at 92 °C for 20 s, an annealing at 58 °C for 65 s, and an extension at 68 °C for 90 s, and a final extension at 60 °C for 5 min.

In addition, the deletion in repeating regions at the 3′ end of the tcdA gene was investigated using the NK9 and NKV011 primers (Table 3) by Kato et al. 1999 [72]. PCR reaction was performed under the same conditions of the multiplex PCR. The thermocycler conditions included a predenaturation at 94 °C for 6 min, followed by 37 cycles of denaturation at 94 °C for 20 s, an annealing at 55 °C for 30 s, and an extension at 60 °C for 120 s, and a final extension at 60 °C for 10 min. The PCR products were visualized using electrophoresis with 1.2% agarose gel and stained with ethidium bromide.

4.3. PCR Ribotyping

PCR ribotyping was performed based on the 16S–23S rRNA intergenic spacer regions described by Bidet et al. 1999 [73]. The primer sequences were 5′-GTGGGCGCTGGATCACCT CCT-3′ (16S primer) and 5′-CCCTGCACCGTTATTACGTTGACC-3′ (23S primer). The PCR reaction was conducted in a total volume of 20 µL composed of 25–200 ng genomic DNA, 0.2 mM dNTPs, 0.2 µM primers, 1.5 mM MgCl₂, 10 × PCR buffer (500 mM KCl, 100 mM Tris-HCl, pH 9.1), 1U Taq DNA polymerase, and deionized water. The thermocycler profile consisted of an initial denaturation at 95 °C for 5 min, followed by 35 cycles of denaturation at 94 °C for 20 s, an annealing at 55 °C for 30 s, and an extension at 60 °C for 120 s, and a final extension at 60 °C for 10 min. The PCR products were visualized using electrophoresis with 1.2% agarose gel and stained with ethidium bromide.
4.4. Quantification of Toxins A and B

Toxigenic *C. difficile* isolates (n = 47) and the reference strain, *C. difficile* R20291, were inoculated on CCFA agar plates. A single colony was cultured in fresh BHI media. A total of 1% of bacterial culture was sub-cultured into fresh BHI media for 48 h at 37 °C. The supernatant was collected from the culture using centrifugation at 5000 × g for 10 min and sterilized by passing through a 0.22 µm membrane. Total protein was measured using Bradford’s assay (Clive G et al., 1989). Indirect enzyme-link immunosorbent assay (ELISA) was performed to quantify the level of toxins A and B. Initially, 96-well polystyrene microtiter plates were coated with 100 µL of 5 mg/mL supernatant in 0.5 M carbonate buffer (pH 9.4) and incubated overnight at 4 °C. The plates were washed three times with 200 µL of 1 × PBS. Then, 200 µL of blocking solution (1% BSA) was added to wells. The plates were incubated for 1 h at room temperature and washed with PBS-T (0.05% Tween-20, pH 7.4). The 100 µL final 1:500 dilution of mouse anti-toxin A (Abcam, Cambridge, UK) or 1:250 dilution of mouse anti-toxin B (Bio-Rad, Hercules, CA, USA) was added to wells. The plates were incubated for 1 h at 37 °C and washed three times with 100 µL of PBS-T at room temperature. Finally, 50 µL of 1:4 dilution of Equilibrate SignalStain® Boost IHC Detection Reagent (HRP, anti-mouse) (Cell Signaling, Beverly, MA, USA) was added to wells. The plates were then incubated for 1 h at 37 °C and washed three times with 1 × PBS. Finally, 100 µL TMAB (3,3′,5,5′-tetramethylbenzidine) substrate (SeraCare, Milford, MA, USA) was added to wells. After 10 min of incubation at 37 °C, the reaction was stopped by addition of 100 µL of 2 N hydrochloric acid. The absorbance at 450 nm was measured by microplate reader (Tecan, Switzerland). The relative levels of toxin production were compared to the reference strain, *C. difficile* R20291.

4.5. Minimal Inhibitory Concentration (MIC) Testing

The minimal inhibitory concentration (MIC) testing was performed using 96-well broth dilution in triplicate. Nine antibiotics, including metronidazole (0.0625–16 µg/mL), vancomycin (0.0625–16 µg/mL), amoxicillin (0.125–32 µg/mL), ampicillin (0.125–32 µg/mL), cefoxitin (2–256 µg/mL), chloramphenicol (0.25–32 µg/mL), levofloxacin (0.125–32 µg/mL), and rifampicin (0.125–32 µg/mL) were subjected to MIC testing. A single colony of *C. difficile* on CCFA was inoculated into fresh BHI medium. After overnight incubation, *C. difficile* culture was transferred to freshly prepared Wilkins-Chalgren broth until the OD$_{600}$ reached 0.6 (~10$^8$ CFU/mL). Two-fold serial dilutions of antibiotics (0.125–512 µg/mL) were prepared in a 96-well plate at a total volume of 200 µL. A total of 10 µL of bacterial suspension (~10$^6$ CFU/mL) was then inoculated into antibiotic plates. The 96-well microplates were incubated at 37 °C under anaerobic conditions for 48 h. The OD$_{600}$ at the end point was measured using a spectrophotometer. The MIC values were defined as the lowest concentration of antibiotic where no growth of bacteria was observed. The MIC results were categorized according to the guidelines of the Clinical and Laboratory Standards Institute (CLSI), http://www.clsi.org/ accessed on 1 June 2021; the European Committee on Antimicrobial Susceptibility Testing (EUCAST), http://www.eucast.org/ accessed on 1 June 2021; and published data [29,30].
