Statistics of Lagrangian quantum turbulence

Christian Beck and Shihan Miah

Queen Mary University of London, School of Mathematical Sciences, Mile End Road, London E1 4NS, UK

We consider the dynamics of small tracer particles in turbulent quantum fluids. The complicated interaction processes of vortex filaments, the quantum constraints on vorticity and the varying influence of both the superfluid and the normal fluid on the tracer particle effectively lead to a superstatistical Langevin-like model that in a certain approximation can be solved analytically. An analytic expression for the PDF of velocity $v$ of the tracer particle is derived that exhibits not only the experimentally observed $v^{-3}$ tails but also the correct behavior near the center of the distribution, in excellent agreement with experimental measurements and numerical simulations. Our results are universal and do not depend on details of the quantum fluid.

Quantum turbulence is a phenomenon of utmost interest in current fluid mechanics research. The turbulent behavior of a quantum liquid such as $^4$He is very different from classical turbulence since vortices are quantized. This means the circulation cannot take arbitrary values as in classical turbulence, and there is also no viscous diffusion of vorticity as in classical turbulence. Recent measurements and simulations have shown that this has profound influence on various measurable observables, most notably the velocity distributions of small test particles embedded in the turbulent flow. Whereas for classical turbulence there is near-Gaussian behavior, one typically observes power laws for quantum turbulence.

The velocity statistics has been subject of several recent papers. Paoletti et al. conducted a seminal experiment using solid hydrogen tracers in turbulent superfluid $^4$He and found that the distribution of velocity components $v_i$ of the tracer particles exhibits a power law $p(v_i) \propto v_i^{-3}$ distribution for large values of $v_i$. Similar results were confirmed by White et al. They performed numerical simulations of quantum turbulence in a trapped Bose-Einstein condensate by calculating solutions of the Gross-Pitaevski equation. The associated PDF of each velocity component $v_i$ was computed directly and it was confirmed that the velocity statistics is non-Gaussian and obeys a power-law distribution $p(v_i) \propto v_i^{-b}$ with $-3.6 < b < -3.3$. In the following, for ease of notation, we often suppress the index $i$. Adachi et al. numerically computed the velocity field of a superflow by calculating the Biot-Savart velocity induced by vortex filaments in steady counterflow turbulence. They found that the resulting PDF exhibits a near-Gaussian distribution in the low-velocity region whereas a power-law $p(v) \propto v^{-3}$ is observed in the high velocity region.

Apparently there is clear evidence from numerical and experimental approaches that power laws in the velocity statistics are highly relevant in quantum turbulence, and that typically the observed power law exponent is close to 3. What is missing so far, however, is a theory of Lagrangian quantum turbulence, by which we mean a theory that consistently describes the dynamics of tracer particles of a given size embedded in the quantum turbulent flow, which would be the proper theoretical tool to explain the observed velocity distributions. Whereas Lagrangian turbulence is a well-established subject area for classical turbulence, very little is known for the quantum case.

In this paper we will introduce a simple but powerful dynamical model of the dynamics of a tracer particle embedded in a quantum liquid. This model will be based on a superstatistical stochastic differential equation. The superstatistics concept, introduced in, has proved to be a very powerful method for modeling a variety of complex systems, including driven nonequilibrium situations and classical hydrodynamic turbulence.

Here, for the first time, we apply this concept to quantum turbulence. The result is a dynamical theory that quite precisely reproduces the observed velocity statistics in quantum turbulence and that also allows for some analytic predictions. In particular, the power law exponent $-3$ follows from our theoretical consideration in a natural way, and moreover a universal prediction for the entire shape of the velocity distribution is obtained, which is in excellent agreement with experimental measurements.

Let us denote the velocity of a Lagrangian tracer particle embedded in the quantum liquid by $v(t)$. We start from a simple local dynamics which will later be extended to a superstatistical model. Consider a linear stochastic differential equation of the form

$$\dot{v}(t) = -\Gamma v(t) + \Sigma L(t)$$

Here $L(t)$ is a rapidly fluctuating stochastic process representing rapid forces in the quantum liquid on a fast time scale, and $\Gamma$ and $\Sigma$ are $3 \times 3$ matrices. The above equation simply says that locally a tracer particle is driven by chaotic forces $L(t)$ from the turbulent flow and at the same time there are damping processes, described by $\Gamma$. Since the chaotic forces act rapidly we approximate $L(t)$ by Gaussian white noise. $\Gamma$ and $\Sigma$ are matrix-valued stochastic processes which evolve on a much larger time scale than $L(t)$. The particle is driven by a mixture of normal and superfluid, and depending on which component dominates, the effective friction described by $\Gamma$ will be very different.

A characteristic property of quantum turbulence is
a spatio-temporally varying vorticity field represented by 1-dimensional topological vortices that reconnect and merge at random moments of time. A test particle may rotate for a short while around a local unit vector $e$ whose direction will be a random variable, describing a given vortex filament in the quantum liquid. Hence, as a special case of eq. (1) we may consider the local dynamics

$$\dot{v} = -\gamma(t)v + \omega [e(t) \times v] + \sigma L(t)$$

(2)

We assume that the damping constant $\gamma$ and the noise strength $\sigma$ are functions of $t$, and so is $\omega$ and the direction of $e$. The second term on the right hand side of eq. (2) represent the rotational movement of the particle around the vortex filament. The unit vector $e$ and the noise strength $\sigma$ evolve stochastically on a large time scale $T_e$ and $T_\sigma$ respectively.

A special coordinate system would be $e = (0, 0, 1)$, then $e \times v = (-v_y, v_x, 0)$ and the velocity components of the particle satisfy

$$\dot{v}_x = -\gamma v_x - \omega v_y + \sigma L_x(t)$$
$$\dot{v}_y = -\gamma v_y + \omega v_x + \sigma L_y(t)$$
$$\dot{v}_z = -\gamma v_z + \sigma L_z(t)$$

(3)

If we introduce a complex variable $z$ by defining $z = v_x + i v_y$, then the $(x, y)$-dynamics can be written as

$$\dot{z} = \dot{v}_x + i \dot{v}_y = (-\gamma + i \omega)z + \sigma (L_x + i L_y)$$

(4)

Forming the average $\langle \cdot \cdot \cdot \rangle$ over all realizations of the noise $L(t)$ one obtains on a time scale where $\gamma$ and $\omega$ are sufficiently constant

$$\langle z(t) \rangle = z(0) e^{-\gamma \cdot \tau} (\cos(\omega t) + i \sin(\omega t))$$

(5)

which is just damped spiraling motion around a local unit vector with frequency $\omega$. We remind the reader that the basic idea of the superstatistics approach is to regard the parameters of a local stochastic differential equation as random variables as well [28]. This means both $\gamma$ and $\omega$ can take on very different values during time evolution, and so can the direction of $e$. A very small $\gamma$ corresponds to nearly undamped motion for a limited amount of time. A very small $\omega$ corresponds to almost no rotation, i.e. straight movement for a limited amount of time. All these cases are included as possible local dynamics and averaged over in the superstatistical approach.

In a quantum turbulent flow, the superfluid component flows without dissipation while being subject to certain quantum mechanical constraints. These quantum restrictions imply that the typical form of rotational motion allowed in the superfluid component is in the form of a thin vortex line, whose circulation around its core is quantized rather than arbitrary as in classical fluids. The magnitude of the velocity field of the fluid particle at distance $r$ from the core of the vortex filament is given by

$$v = |v| = \frac{\kappa}{2\pi r}$$

(6)

where $\kappa = \frac{\hbar}{m} \approx 9.97 \times 10^{-4} cm^2/s$ is the quantum of circulation, $\hbar$ is Planck’s constant and $m$ is the mass of the fluid atom, in our case helium.

If the tracer particle comes close to a vortex filament, it will typically follow a circular path around the vortex filament, with $v = \frac{\kappa}{2\pi r} = \frac{\kappa}{2\pi r}$, where $T$ is the period of one rotation. Note that the angular frequency entering eq. (4) is thus $\omega = \frac{\kappa}{T} = \frac{\kappa}{2\pi T}$.

For an ordinary spherical Brownian particle in a viscous liquid one has constant damping due to Stoke’s law:

$$\gamma = \frac{6\pi \nu \rho a}{M}$$

(7)

Here $\nu$ is the kinematic viscosity of the liquid, $\rho$ is the fluid density, $M$ is the mass and $a$ the radius of the tracer particle.

For quantum turbulence, the effective dissipation acting on the tracer particle is influenced by many competing effects, and it fluctuates strongly depending on whether the particle is close to a vortex filament or not. Far away from a vortex filament, the movement will be dominated by Brownian motion similar as in a normal liquid, whereas close to a vortex filament the movement will be very rapid and almost friction free, dominated by the superfluid.

To take into account the fact that the effective friction in eq. (2) is fluctuating, we may write quite generally

$$\gamma = \frac{1}{L^2} \sum_{i=1}^{n} X_i^2$$

(8)

where $L$ is a characteristic length scale and the $X_i$ are dimensionless random variables that evolve in time and space. We have squared the random variables because for physical reasons $\gamma$ must always be positive, though values close to $0$ are possible. $n$ denotes the number of degrees of freedoms that influence the fluctuating effective friction. Of course, the simplest model is to assume that the $X_i$ are a rescaled sum of many microscopic random variables that act almost independently. Thus the Central Limit Theorem suggests to assume that the $X_i$ are Gaussian random variables.

The quantum mechanical constraint given in Eq. (6) tells us that the average rotational velocity of the tracer particle is very high near the vortex core (for small distance $r$). Therefore, the effective viscosity $\gamma$ acting on the tracer particle in eq. (2) is small if the particle is very near to the vortex core. This means that $\sum_i X_i^2$ is small. On the other hand, if the test particle is very far from the
vortex filament, then \( \gamma \) is large and the friction effects are strong, mainly due to the normal fluid component. This suggests the physical interpretation that the \( X_i \)'s may just be identified with the perpendicular distances of the test particle from the nearest vortex filament. The vortex filaments themselves of course evolve in a highly complicated stochastic way. Since only the distance perpendicular to the nearest vortex filament is relevant, for a 3-dimensional quantum liquid we have \( n = 2 \), that is two degrees of freedom. The distance \( r \) of the test particle from the vortex filament becomes a random variable given by

\[
  r^2 = (X_1^2 + X_2^2) L^2, \tag{9}
\]

where again \( L \) is a suitable spatial scale introduced for dimensional reasons.

We may estimate this length scale \( L \) as follows: For large distances \( r \), of the order of average vortex filament distance \( d \) in the turbulent flow, the tracer particle follows nearly normal type of Brownian motion, with Stokes law \( \beta \) valid in good approximation. Putting \( r = \frac{d}{2} \) into eq. (9), (5) and (7) one arrives at the following estimate for the length scale \( L \):

\[
  L = \left( \frac{M a^2}{24 \pi \rho a} \right)^{\frac{1}{4}} \tag{10}
\]

Clearly, our model requires small particles with \( a << d \), if larger scales \( a >> d \) are probed, one just gets ordinary Brownian motion with Gaussian behavior \([28, 29]\).

The velocity distribution of the small tracer particle in the quantum turbulent flow described by eq. (2) can now be calculated by using standard techniques of superstatistics \([21]\). We first assume, for simplicity, a constant \( \gamma \) and define the parameter \( \beta := \frac{n}{\gamma} \), which in equilibrium statistical mechanics corresponds to the inverse temperature, whereas here it is more a measure of distance from the nearest vortex filament. On time scales \( t \) satisfying \( \gamma^{-1} < t < T_r \), the stationary distribution of the tracer particle described by Eq. (14) for fixed \( \beta = \frac{2}{\gamma} \) is given by the Gaussian distribution

\[
  p(v|\beta) = \sqrt{\frac{\beta}{2\pi}} e^{-\frac{1}{2} \beta v^2}, \tag{11}
\]

assuming uniform distribution of the random vectors \( e \).

The situation becomes different for fluctuating \( \beta \), that is, if one allows the parameters \( \gamma \) (or \( \sigma \)) in Eq. (14) to be varying as well. Assuming that \( X_1, \ldots, X_n \) are independent Gaussian random variables, the resulting distribution of \( \beta = \sum_{i=1}^n X_i^2 \) is a \( \chi^2 \) distribution of degree \( n \), i.e.

\[
  f(\beta) = \frac{1}{\Gamma(\frac{n}{2})} \left( \frac{n}{2} \beta_0 \right)^{\frac{n}{2} - 1} \beta^{-\frac{n}{2}} e^{-\frac{n}{2} \beta_0}. \tag{12}
\]

The average of the fluctuating \( \beta \) is given by

\[
  \langle \beta \rangle = n \langle X_i^2 \rangle = \int_0^\infty \beta f(\beta) \, d\beta = \beta_0 \tag{13}
\]

and the variance by

\[
  \langle \beta^2 \rangle - \beta_0^2 = \frac{2}{n} \beta_0^2 \tag{14}
\]

The probability density to observe the velocity \( v \) of the test particle for any value of \( \beta \) is given by the marginal probability \( p(v) \) as follows

\[
  p(v) = \int_0^\infty f(\beta) p(v|\beta) \, d\beta \tag{15}
\]

Substituting \( p(v|\beta) \) and \( f(\beta) \) from Eq. (11) and Eq. (12) into Eq. (15), we obtain after a short calculation

\[
  p(v) = \frac{\Gamma\left(\frac{n}{2} + \frac{1}{2}\right)}{\Gamma\left(\frac{n}{2}\right)} \left( \frac{\beta_0}{\pi n} \right)^{\frac{n}{2}} \frac{1}{\left(1 + \frac{\beta_0}{\pi n} v^2\right)^{\frac{n}{2} + \frac{1}{2}}} \tag{16}
\]

These types of distributions play an important role in \( q \)-generalized versions of statistical mechanics \([30]\), with the entropic index \( q \) related to the parameter \( n \) by \( q = 1 + \frac{2}{n+1} \).

As we mentioned earlier the velocity of the tracer particle depends on the perpendicular distance between the particle and the nearest evolving (and sometimes merging) vortex filament. Therefore, the relevant degrees of freedom are \( n = 2 \) for 3-dimensional quantum turbulence. By substituting \( n = 2 \) in Eq. (16) one obtains

\[
  p(v) = \frac{\sqrt{\beta_0}}{(2 + \beta_0 v^2)^{\frac{3}{2}}} \tag{17}
\]

Clearly, for large \( v \) this implies power-law tails

\[
  p(v) \propto v^{-3}. \tag{18}
\]

The remarkable result, however, is that we do not only get the power law tails but a concrete prediction for the entire shape of the probability distribution, including the region near the maximum.

The probability distribution of kinetic energy \( E \) can be calculated from Eq. (16) by using a simple transformation of random variables. For a particle of unit mass \( E = g(v) = \frac{1}{2} v^2 \), hence \( v = g^{-1}(E) = \sqrt{2E} \) and

\[
  p_E(E) \, dE = p_v(v) \, 2dE, \tag{19}
\]

the factor 2 coming from the fact that there are two solutions \( \pm v \) for the same energy \( E \). This leads to the probability distribution of energy

\[
  p_E(E) = 2p_v \left( g^{-1}(E) \right) \left| \frac{dg^{-1}(E)}{dE} \right| \tag{20}
\]

For \( n = 2 \) this predicts power law tails proportional to \( E^{-2} \) for large \( E \).
FIG. 1: Experimental data of Paoletti et al [1] and a fit using eq. (21) with variance parameter $\beta_0 = 4.5$ and $c = -0.12$ for $v_x$, respectively $c = 0.54$ for $v_z$

So far our model was based on a situation where the average velocity $\bar{v}$ of the particle is zero. Of course, in experiments there is often a drift velocity in the system that gives a non-zero mean velocity $c$ to the test particle. In this case one has to replace $v$ by $v - c$ in the model equations we derived so far, and for $n = 2$ one ends up with

$$p(v) = \frac{\sqrt{\beta_0}}{(2 + \beta_0(v - c)^2)^{\frac{3}{2}}}$$

(21)

Let us now compare our model prediction with the experimental data obtained by Paoletti et al. Fig. 1 shows the experimental data for both velocity components $v_x$ and $v_z$, and a fit by our analytic formula. An excellent fit is obtained. It is remarkable that the fit is not only correctly producing the power law tails but also the vicinity of the maximum. To illustrate this, Fig. 2 shows the same data in a linear plot.

Let us mention that our model directly predicts the power law exponent $-3$ in a universal way. The value $-3$ is a consequence of the fact that vortex filaments are thin 1-dimensional structures embedded into 3-dimensional space, thus leading to $n = 2$ in eq. (4). Our model also correctly reproduces the $E^{-2}$ tails of the energy spectrum observed by Paoletti et al.

Finally, we can also predict the value $\beta_0 \simeq 4.5$ of the variance parameter to be used in eq. (21). So see this, let us recall that Paoletti et al., in their experiment [1], rescaled their measured velocity data to variance 1. In these units their maximum velocity measured was $v_{\text{max}} \simeq 10$ (see Fig. 1). Strictly speaking, the variance does not exist for any distribution that decays as $v^{-3}$ for large $|v|$, but what exists is of course the variance as calculated for a given experimental cutoff $v_{\text{max}}$. From

$$1 = \langle v^2 \rangle \simeq 2 \int_0^{v_{\text{max}}} p(v)v^2\,dv \simeq \frac{2}{\beta_0} \log v_{\text{max}}$$

(22)

we obtain the predicted value $\beta_0 \simeq 2 \log v_{\text{max}} \approx 4.6$, in agreement with what yields the optimum fit in Fig. 1. Thus, besides the (nonuniversal) systematic drift velocity $c$, all relevant parameters are predicted from first principles.

To conclude, in this paper we have developed a super-statistical dynamical model of Lagrangian quantum turbulence. This model predicts that the velocity statistics of small tracer particles in a quantum turbulent flow obey a power law distribution $p(v) \propto v^{-3}$ and the distribution of energy follows a power law as well, i.e. $p(E) \propto E^{-2}$. These results are in excellent agreement with Paoletti et al.’s measurements [1] as well as with the numerical results obtained by other authors [2, 3]. Our theory provides a universal prediction given by (21) for both the center and the tail parts of the velocity distribution. The underlying stochastic model arises quite naturally out of the fact that small tracer particles see fluctuating effective frictions, depending on the distance to the nearest vortex filament.
