A vinyl silylsilylene and its activation of strong homo- and heteroatomic bonds†

Matthew M. D. Roy, Michael J. Ferguson, Robert McDonald, Yuqiao Zhou and Eric Rivard

The facile synthesis of a rare two-coordinate acyclic silylene (R₂Si:) that is stabilized using a bulky vinylic N-heterocyclic olefin ligand and the strongly σ-donating hypersilyl group [Si(SiMe₃)₃]⁻ is reported. This vinyl-substituted silylene exhibits an excellent combination of prolonged thermal stability along with high reactivity towards small molecules. Despite being stable for months in solution, the reactivity of this new silylene is manifest in its ambient temperature activation of strong B–H, Si–Cl, O–C, P–P and C–H bonds.

Results and discussion

This study relied upon the steric bulk and potential 4-electron (2σ, 2π) donating ability of the carbon-based anionic vinylic hypervalent ligand [MePr═CH]⁻,¹ to gain access to a two-coordinate silylene. This ligand represents the deprotonated form of its neutral N-heterocyclic olefin (NHO)₁² parent MePr═CH₂, and this vinyllic ligand has been previously used in our group to isolate the first base-free divinylgermylene (MePrCH)₂Ge.¹³

The first step towards accessing a new organosilylene was to install the [MePr═CH]⁻ ligand at silicon. This was achieved by the synthesis of the silane (MePrCH)SiBr₃ (1) from mixing two equivalents of the olefin preequilibrated MePr═CH₂ and SiBr₃. After filtration from the flocculant (MePrCH)Br precipitate, the

---

Introduction

The activation and functionalization of small molecules such as H₂, CO, CO₂, P₄,¹ and even N₂,² by Earth-abundant main group elements usually relies on the isolation of highly reactive element centers. In order to be synthetically viable, a delicate balance of stability and reactivity must be achieved. Amongst p-block compounds, those of Group 14 in the +II oxidation state (tetrelenes) have shown significant promise with regard to bond activation and catalysis.³ Silylenes, (R₂Si:), still remain rare relative to the other Group 14 tetrelenes, owing in part to the general instability of Si⁺⁺ compounds.⁴

While coordinatively saturated examples of silylenes (e.g. Cp*₂Si; Cp* = η⁵-C₅Me₅) had been reported previously,³ West and coworkers prepared the first example of an unsaturated two-coordinate N-heterocyclic silylene.⁵ It was only in 2012 that the first examples of isolable two-coordinate acyclic silylenes were simultaneously published (I and II, Scheme 1)⁶ in stark contrast, their heavier R₂E: congeners (E = Ge, Sn, Pb; R = anionic ligand) were first reported decades prior.⁶ While a few examples of room temperature stable acyclic silylenes are known,⁷,⁸ all have been stabilized by two heteroatom-based ligands. Herein, we utilize a bulky vinylic ligand [MePr═CH]⁻,¹ (MePr = ([MeCN(Dipp)]₂C); Dipp = 2,6-Pr₂C₆H₄) to generate the first two-coordinate acyclic silylene stabilized by a carbon-based donor.¹⁰ Despite the remarkable thermal stability of the title complex (MePrCH)Si(Si(SiMe₃)₃), this vinyl silylsilylene was able to undergo the formal oxidative addition of several strong organic and inorganic bonds, including the regioselective activation/functionality of white phosphorus (P₄) and the activation of a primary C–H bond at room temperature.

Scheme 1  The first isolable two-coordinate acyclic silylenes (I and II) and the spectroscopically observed iminosilylene III.
target Si^IV^ precursor 1 was isolated as an off-white, crystalline solid in a 53% yield (Scheme 2). Attempts to prepare the divinyl silane ([MeIPrCH])SiBr2 by combining 1 with an additional two equivalents of [MeIPr]−CH2 or one equivalent of [MeIPrCH(SiMe3)]11 were unsuccessful. We then focused our synthetic studies on preparing a silylene directly from 1.

Following recent reports of bulky silyl-substituted silylenes,15,16 ([MeIPrCH])SiBr2 (1) was combined with two equivalents of hypersilyl potassium [K(THF)][Si(SiMe3)] in toluene (Scheme 2). This resulted in the immediate formation of deep green slurry. 1H NMR spectroscopic analysis of the filtrate revealed quantitative conversion to a 1 : 1 mixture of a new [MeIPr]−CH2 containing product and BrSi(SiMe3). The vinylic proton signal in the new product exhibited two-bond coupling satellites to Si (|Jh,si| = 13.5 Hz), and its remarkably downfield-positioned chemical shift (δ 7.40 in C6D6) indicates significant transfer of electron density from the [MeIPr]−CH2 ligand to silicon. Additionally, the $^{29}$Si$^1$H NMR spectrum displayed a signal at 432.9 ppm, which lies in the spectral range of known two-coordinate acyclic silylenes.9

To confirm the formation of the two-coordinate silylene ([MeIPrCH]Si[Si(SiMe3)]2) (2), deep-green crystals suitable for X-ray crystallographic analysis were grown from Me3SiOSiMe3. The molecular structure of 2 (Fig. 1) is in good agreement with the abovementioned NMR results. Specifically, the vinylic C3–C4 bond in 2 [1.406(3) Å] is elongated relative to free NHO MeIPr=CH2 [1.3489(18) Å],13 providing added evidence for the transfer of σ-electron density to silicon. The C4–Si1–Si2 angle was found to be 101.59(7)°, in line with the presence of a high degree of s-character at the silicon-based lone pair. This angle implies that 2 should have a good balance of stability and reactivity. For example, the colorless dithiolato-supported silylene Si(SA[Me$^3$])2 (I in Scheme 1) has an R–Si–R angle of 90.519(19)° indicating a relatively low-energy Si-based lone pair of pure s-character.7a While this molecule has not been reported to cleave strong organic bonds,14 acyclic silylenes with obtuse R–Si–R angles (and smaller HOMO–LUMO gaps) have been shown to activate small molecules such as H2, CO2, and NH3.7k–9

([MeIPrCH]Si[Si(SiMe3)]2) (2) is remarkably stable, with no NMR spectroscopic sign of decomposition noted after storage of a benzene solution at room temperature for two months (under N2 atmosphere). This observation contrasts the situation in Inoue and Rieger’s imino silylsilene (III, Scheme 1), which exists predominately in a 7-membered Si^IV^ ring (silepin) form (via reversible ligand activation) at ambient temperature.15 Furthermore, our group’s attempts to generate the bisiminosilylene (IPrN)Si2 consistently afforded irreversible ligand activation products.15 Additionally, silylenes generated using hypersilyl potassium are often contaminated with the highly soluble BrSi(SiMe3)3 byproduct,15 however in our case pure 2 can be obtained in moderate yield (67%) by washing the crude residue with a minimal amount of cold (−30 °C) Me3SiOSiMe3.

To gain further insight into the influence of the [MeIPr]−CH2 ligand in 2, we conducted a series of computational (DFT) studies at the M06-2X/def2-TZVP level.16 The computed HOMO of 2 is predominately a silicon-based lone pair whereas the HOMO−1 consists of a C−Si π bond between the vinylic ligand and the silylene center (Fig. 2). The C−Si Wiberg Bond Index (WBI) was found to be 1.06 and the LUMO shows significant C−Si π* orbital character. Natural Resonance Theory (NRT) analysis further supports this bonding description, as three of the most relevant resonance structures (Fig. 2, structures B, C and D) have been shown to activate small molecules such as H2, CO2, and NH3.
contain a C–Si π bond with a combined 61.1% weighting of these structures. Together, these analyses demonstrate the stabilizing π-donation ability of the $^{21}$IPr═CH$^-$ ligand. Additionally, the computed natural charges show a highly polarized Si—I—Si bond (SiI$: +0.54$; SiI$: -0.51$) which may enable interesting reactivity to transpire. As a result, we explored the interaction of 2 with small molecules in detail.

We began a reactivity study of 2 by combining this silylene with the carbon-based electrophile MeOTf (OTf = CF$_3$SO$_3$). As anticipated, the deep green color of 2 dissipated upon addition of MeOTf and NMR analysis revealed the formation of a single new product. X-ray crystallography identified this species as the new triflato-silane $^{[46]}$PrCH$^-$Si[Me]OTf$^-$[SiMe$_3$]$^-$) (3) (Scheme 3, Fig. 3). Compound 3 crystallizes in a distorted tetrahedral geometry, with a covalently bound -OTf unit in the solid state (Fig. 3). Compound 3 showed a singlet Si resonance in the $^{1}$HNMR spectrum (d 3.61 ppm, J$_{HH}$ = 1.80 Hz). The lack of $J_{HH}$ coupling to the neighboring vinyl hydrogen implied that oxidative addition of an Si–Cl bond had transpired in place of Si–H bond activation.$^{17}$ Crystallographic analysis confirmed the formation of $^{[46]}$PrCH$^-$SiCl$^-$[H]$^-$Cl$^-$[SiMe$_3$]$^-$) (5) (Fig. 4). Of note, the addition of HSiCl$_3$ across a silylene (such as Cl$_2$Si) is a key step proposed in the chemical vapour deposition (CVD) of epitaxial silicon from trichlorosilane.$^{18}$ The sterically congested nature of 5 is evident by its $^1$H and $^{13}$C$^-$NMR spectra which are very broad at room temperature but are resolved at +75°C. The molecular structure of 5 (Fig. 4) shows an expected distorted tetrahedral geometry at Si1 [Si1–Si2–Si3: 109.81(9); C4–Si1–O1: 118.15(19)]. While acyclic silylenes have not yet been shown to react with P$_4$, several examples of cyclic silylenes reacting with P$_4$ are known. These reactions are limited to the oxidative addition of a single P–P bond across a silicon center,$^{20}$ and the controlled activation/functionnalization of P$_4$ by main group elements remains a difficult transformation.$^{21}$ Upon mixing 2 and P$_4$ for 20 minutes at room temperature, a pale orange solution was formed.$^{31}$P$^-$NMR analysis suggested that simple oxidative addition of a P–P bond had not occurred, as three distinct signals were observed (d 120.0,−181.0,−316.7 ppm).$^{22}$ X-ray crystallographic analysis revealed that a 1,2-migration of the hypervinyl group of 2 transpired in addition to P$_4$ reduction (Scheme 3, Fig. 5) to yield $^{[46]}$PrCH$^-$Si(P$_4$)$^-$[SiMe$_3$]$^-$) (6). This transformation is likely facilitated by the steric bulk of 2 and the polarized nature of the Si—I—Si bond (vide supra). While the mechanism of this reaction likely involves first the oxidative addition of a P–P bond of P$_4$ to silylene 2, followed by a 1,2-silyl migration, we did not observe any experimental evidence for

**Scheme 3** Oxidative addition of the substrates MeOTf (3), HBpin (4), HSiCl$_3$ (5) and P$_4$ (6) to the reactive silylene 2.

**Fig. 3** Molecular structure of $^{[46]}$PrCH$^-$Si[Me]OTf$^-$[SiMe$_3$]$^-$ (4) with thermal ellipsoids plotted at a 30% probability level. All hydrogen atoms (except the vinyllic hydrogen and silane hydrogen) were omitted for clarity. Selected bond lengths [Å] and angles [°]: C1–C4 1.394(7), C4–Si1 1.789(5), Si1–Si2 2.364(2), Si1–C11 2.170(2), Si2–H2 1.507(7), Si2–C12 2.076(3), 2.074(3), Si1–Si3 2.358(2), Si2–Si1–Si3 109.81(9), Si2–Si1–C11 100.27(9), Si2–Si1–C4 118.15(19).
this postulated oxidative addition intermediate.\(^{22}\) The observed activation/functionalization of P\(_4\) by \(\text{BuNCO}\) represents the cleavage of two P–P bonds and the regioselective formation of four new Si–P bonds. Remarkably, a search of the Cambridge Structural Database (CSD) revealed that compound 6 represents an entirely new bonding motif for the P\(_4\) \(^{2}\) ligand.\(^{23}\) Notably, silylated phosphines and phosphides are valuable precursors to element phosphide nanomaterials\(^{24}\) and organophosphines\(^{25}\) and thus their preparation from elemental phosphorus continues to be of great importance.

Following the remarkable report by Rieger, Inoue and coworkers of an isolable three-coordinate silanone (formed by oxidation of III in Scheme 1 with N\(_2\)O)\(^{26}\) we wondered whether 2 would react in a similar manner. Surprisingly, exposure of a solution of 2 to an N\(_2\)O atmosphere at \(-78\) °C or room temperature afforded no reaction. Subsequently, 2 was combined with one equivalent of the potential oxygen-atom source tert-butyl isocyanate (\(\text{BuNCO}\)) which yielded a mixture of products by \(^1\)H NMR spectroscopy, including several \(^{31}\)P=\(^{13}\)C-containing species, unreacted \(\text{BuNCO}\) and isobutylene. Extraction of the mixture with hexanes and crystallization afforded crystals of the silyl-cyanide (MeIPrCH)SiH(CN)\{Si(SiMe\(_3\))\(_2\)\} (7) in low (31\%) yield (Fig. 6). Compound 7 is likely formed from the isocyanide (\(\text{BuNCO}\)) by-product generated after the initial oxidation of 2 with \(\text{BuNCO}\) (Scheme 4). Thus far, we have been unable to isolate and identify the other products in the mixture, including the possible silanone by-product (MeIPrCH)Si(O){Si(SiMe\(_3\))\(_2\)}. In order to give credence to the proposed mechanism, 2 was combined with one equivalent of \(\text{BuNC}\), which led to the quantitative formation of a 1 : 1 mixture of 7 and isobutylene (as determined by \(^1\)H NMR spectroscopy). This transformation represents a quantitative room temperature activation of a primary C–H bond by a silylene (R\(_2\)Si). Related transformations have been demonstrated previously with an acyclic germylene\(^{27}\) and a disilene,\(^{28}\) albeit at elevated temperatures.

### Conclusions

In this work, the synthesis of a thermally stable, two-coordinate acyclic silylene (MeIPrCH)Si{Si(SiMe\(_3\))\(_2\}) was achieved, and is the first example of such a species supported by a carbon-based ligand. The stabilizing influence of [\(^{31}\)P=\(^{13}\)C] was evaluated experimentally and computationally. The high reactivity of this new silylene was demonstrated by its room temperature activations of strong homo- and heteroatomic bonds. Future work will target the synthesis of more nucleophilic sources of [\(^{31}\)P=\(^{13}\)C] which may allow for the formation of a stable divinysilylene and related reactive species for main group element-based catalysis.

In an attempt to observe this potential intermediate, the reaction of $2 + P_4$ was monitored by $^{31}P\{^{1}H\}$ NMR spectroscopy in toluene-d$_8$. At $-80$ °C, we observed only $6$ + unreacted $P_4$. At $-60$ °C and above, several new signals were observed, however none of the signals clearly correspond to a $P_4$-containing intermediate. In contrast, when the reaction of $2 + P_4$ was monitored by $^{31}P\{^{1}H\}$ NMR at room temperature, clean conversion to $6$ was observed. This divergent reactivity may be due to significantly different solubilities of $P_4$ and $2$ at low temperature, thus altering the effective stoichiometry in solution.
