(Dated: May 2, 2014)

In a microcanonical ensemble (constant $NVE$, hard reflecting walls) and in a molecular dynamics ensemble (constant $NVE$, periodic boundary conditions) with a number $N$ of hard spheres in a $d$-dimensional volume $V$ having a total energy $E$, a total momentum $P$, and an overall center of mass position $G$, the individual velocity components, velocity moduli, and energies follow transformed beta distributions with different arguments and shape parameters depending on $d$, $N$, $E$, the boundary conditions, and possible symmetries in the initial conditions. This can be shown marginalizing the joint distribution of individual energies, which is a symmetric Dirichlet distribution. In the thermodynamic limit the beta distributions converge to gamma distributions with different arguments and shape or scale parameters, corresponding respectively to the Gaussian, i.e., Maxwell-Boltzmann, Maxwell, and Boltzmann or Boltzmann-Gibbs distribution. These analytical results are in agreement with molecular dynamics and Monte Carlo simulations with different numbers of hard disks or spheres and hard reflecting walls or periodic boundary conditions.

I. INTRODUCTION

The problem of the velocity distribution in a gas of hard spheres was discussed in a paper published by Maxwell in 1860 [1]. Maxwell obtained the velocity distribution by assuming independence of the three components of velocity and rotational invariance of the joint distribution. The only distribution satisfying the functional equation

$$f_v(x_1, x_2, x_3) = \Phi(x_1^2 + x_2^2 + x_3^2)$$

has factors of the form

$$f_v(\alpha) = A \exp(-Bx^2),$$

$\alpha = 1, 2, 3$. This simple heuristic derivation can still be found in modern textbooks in statistical physics or physical chemistry [2], but generalizations of Maxwell’s method appeared earlier in the physical literature [3].

In 1867 Maxwell [4] became aware that Eq. (2) should appear as a stationary solution for the dynamics of the gas and introduced a concept that later was called Stoßzahlansatz by Boltzmann. It led to a more detailed study of molecular collisions and to kinetic equations whose stationary solutions coincide with Maxwell’s original distribution (see Refs. [5, 6] for a modern mathematical approach to kinetic equations). This route was followed by Boltzmann, who obtained the velocity distribution in a more general way in a series of papers written between 1868 and 1871 [11, 12]. Based on the Stoßzahlansatz, Boltzmann could prove that Maxwell’s distribution is stationary. These results are summarized in Tolman’s book [13] and in the first chapter of ter Haar’s book [14].

The two physicists were not working in isolation and were aware of their respective works. In his 1872 paper, Boltzmann often quotes Maxwell [15]. In 1873, Maxwell wrote to his correspondent Tait [16]:

“By the study of Boltzmann I have been unable to understand him. He could not understand me on account of my shortness, and his length was and is an equal stumbling block to me.”

More details on the relationship between Maxwell and Boltzmann and on the influence of Maxwell on Boltzmann’s thought have been collected by Uffink [17].

Tolman’s analysis of classical binary collisions for hard spheres led to rate equations which can be interpreted as transition probabilities for a Markov chain after proper normalization. The interested reader can consult chapter V of Tolman’s classic book [13], in particular the discussion around Eq. (45.3) on page 129. The connection with Markov chains was made explicit by Costan-
tini and Garibaldi [18, 19], who used a model due to 
Brillouin [20]. Before Costantini and Garibaldi, Penrose suggested that a Markovian hypothesis could justify the use of standard statistical mechanical tools [21]. According to our interpretation of Penrose, due to the limits in human knowledge naturally leading to coarse graining, systems of many interacting particles effectively behave as Markov chains. Moreover, the possible number of states of such a chain is finite even if very large, therefore only the theory of finite Markov chains is useful. Statistical equilibrium is reached when the system states obey the equilibrium distribution of the finite Markov chain; this equilibrium distribution exists, is unique and coincides with the stationary distribution if the chain is irreducible or ergodic. This point of view is also known as Markovianism. Indeed, in a recent paper on the Ehrenfest urn, we showed that, after appropriate coarse graining, a Markov chain well approximates the behaviour of a realistic model for a fluid [22].

Here we study the velocity distribution in a system of $N$ smooth elastic hard spheres in $d$ dimensions. Even if the evolution of the system is deterministic, we can consider the velocity components of each particle as random variables. We do not consider a finitary [23] version of the model by discretizing velocities, but keep them as real variables. Then a heuristic justification of Eq. (2) can be based on the central limit theorem (CLT). Here is the argument. Following Maxwell’s idea, one can consider the velocity components of each particle independent from each other. Further assuming that velocity jumps after collisions are independent and identically distributed random variables, one obtains for the velocity component $\alpha$ of a particle $i$ at time $t$

$$v_{i\alpha}(t) = v_{i\alpha}(0) + \sum_{j=1}^{n(t)} \Delta v_{i\alpha,j}, \quad (3)$$

where $n(t)$ is the number of collisions for that particle up to time $t$ and $\Delta v_{i\alpha,j}$ is the change in velocity at collision $j$. If the hypotheses stated above are valid, Eq. (3) defines a continuous-time random walk and the distribution function $f_{v_{i\alpha}}(x, t)$ approaches a normal distribution for large $t$ as a consequence of the CLT. Unfortunately this argument is only approximately true in the case of large systems and false for smaller systems.

In Sec. II we obtain the theoretical probability density functions of the individual energies, velocity moduli and velocity components, starting from the fundamental uniform distribution law in phase space. In Sec. III we present the molecular dynamics method used to simulate hard spheres. Interestingly, the same distributions can be reproduced by a simple Monte Carlo stochastic model introduced in Sec. IV. The numerical results are presented in Sec. V, together with some statistical goodness-of-fit tests. Indeed, it turns out that an equilibrium distribution of the velocity components seems to be reached already for $N = 2$ particles and without using any coarse graining. When $N$ grows the equilibrium distribution approaches the normal distribution, Eq. (2). A discussion and a summary follow in Sec. VI.

II. THEORY

We consider a fluid of $N$ hard spheres in $d$ dimensions with the same diameter $\sigma$ and mass $m$ in a cuboidal box with sides $L_\alpha$, $\alpha = 1, \ldots, d$. The positions $\mathbf{r}_i$, $i = 1, \ldots, N$ are confined to a $d$-dimensional box with volume $V = \prod_{\alpha=1}^{d} L_\alpha$, i.e., each position component $r_{i\alpha}$ can vary in the interval $[-L_\alpha/2, L_\alpha/2]$. Elastic collisions transfer kinetic energy between the particles, while the total energy of the system,

$$E = \frac{1}{2} \sum_{i=1}^{N} m_i \mathbf{v}_i \cdot \mathbf{v}_i = \frac{1}{2} m \mathbf{v} \cdot \mathbf{v}, \quad (4)$$

does not change in time, i.e., it is a constant of the motion. Therefore, the velocities $\mathbf{v}_i$ are confined to the surface of a hypersphere given by the constraint that the total energy is $E$, i.e., each velocity component $v_{i\alpha}$ can vary in the interval $[-\sqrt{2E/m}, \sqrt{2E/m}]$ with the restriction on the sum of the squares given by Eq. (4). In other words, the rescaled positions $\mathbf{q}$ with $q_{i\alpha} = r_{i\alpha}/L_\alpha$ are confined to the unit hypercube in $dN$ dimensions, while the rescaled velocity components $\mathbf{u} = \sqrt{m/(2E)} \mathbf{v}$ are confined to the surface of the unit hypersphere in $dN$ dimensions defined by the constraint $\mathbf{u} \cdot \mathbf{u} = 1$.

The state of the system is specified by the phase space vector of all velocities and positions $\Gamma = (\mathbf{v}, \mathbf{r})$, i.e., by $2dN$ variables: the velocity components $v_{i\alpha}$ and the position components $r_{i\alpha}$. However, these variables are not independent because of constraints. For spheres with random velocities and positions confined in a container with hard reflecting walls, the total energy $E$ is conserved (microcanonical ensemble, constant $NVE$) and thus the number of independent variables is $g = 2dN - 1$. With periodic boundary conditions also the total linear momentum

$$\mathbf{P} = \sum_{i=1}^{N} m_i \mathbf{v}_i = m \sum_{i=1}^{N} \mathbf{v}_i \quad (5)$$

and center of mass

$$\mathbf{G} = \frac{\sum_{i=1}^{N} m_i \mathbf{r}_i}{\sum_{i=1}^{N} m_i} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{r}_i \quad (6)$$

are conserved (molecular dynamics ensemble, constant $NVE\Gamma$), and thus the number of independent variables drops to $g = 2d(N-1) - 1 = 2dN - 2d - 1$. Symmetries in the positions and velocities may reduce $g$ too; e.g., if all components $i$ of $\Gamma$ are pairwise symmetric with respect to the origin, with both kinds of boundary conditions this point symmetry will stay on forever and $g = dN - 1$ or $g = 2d(N/2 - 1) - 1 = dN - 2d - 1$ respectively. For the sake of simplicity, in presenting the theory we
will treat explicitly only the microcanonical case without symmetries.

Following Khinchin, one can assume the uniform distribution in the accessible portion of phase space as the starting point of statistical mechanics \[24\]. In our case, the measure of the accessible region of phase space is the product of the volume of the \(dN\)-dimensional hypercube times the surface of the \(dN\)-dimensional hypersphere,

\[
\Omega = V^N \frac{2\pi^{dN/2}}{\Gamma(dN/2)} \left( \frac{2E}{m} \right)^{(dN-1)/2}.
\]  

(7)

This applies to a phase space whose coordinates are velocities and positions; of course the expression will be slightly different using momenta rather than velocities, or if the so-called density of states with respect to the energy, \(\Omega' = d\Omega/dE\), is used instead \[24\].

Khinchin’s Ansatz is that the probability density function (PDF) for points \((v, r)\) in the permitted region of phase space is uniform. However, so far this has not been rigorously proved in general. In our case this Ansatz leads to the joint PDF for velocities and positions

\[
f_{v, r}(x, y) = \frac{1}{\Omega^*} \mathbb{1}_{\{x = \frac{2\mathbb{E}}{m}\}}(y) \prod_{i=1}^{dN} \mathbb{1}_{\{a_i, \epsilon_i, \delta_i \}}(y),
\]

(8)

where \(1_A(x)\) is the indicator function of the set \(A\),

\[
1_A(x) = \begin{cases} 1 & \text{if } x \in A \\ 0 & \text{if } x \notin A \end{cases}.
\]

(9)

As the energy does not depend on positions, one can integrate over the latter, yielding a uniform PDF for particle velocities on the surface of a hypersphere,

\[
f_v(x) = \frac{\Gamma(dN/2)}{2\pi^{dN/2}} \left( \frac{m}{2E} \right)^{(dN-1)/2} \mathbb{1}_{\{x = \frac{2\mathbb{E}}{m}\}}(x).
\]

(10)

The marginalization of this joint PDF leads to the distributions of individual particle energies as well as of velocity moduli and velocity components. To this purpose, it is convenient to study the relationship between Eq. (10) and the symmetric Dirichlet distribution with parameter \(a\).

The PDF of the \(n\)-dimensional Dirichlet distribution with parameter vector \(a\) is

\[
f^D_D(x; a) = \frac{1}{B(a)} \prod_{i=1}^{dN} \frac{x_i^{a_i-1}}{\Gamma(a_i)} \prod_{i=1}^{n} \mathbb{1}_{\{0 \leq x_i \leq 1\}}(x),
\]

(11)

Its value is zero outside the unit simplex

\[
S = \left\{ x = \mathbb{E}^n : \forall x_i \geq 0 \wedge \sum_{i=1}^{n} x_i = 1 \right\},
\]

(12)

and thus Eq. (11) can also be written

\[
f^D_D(x; a) = \frac{1}{B(a)} \prod_{i=1}^{dN} x_i^{a_i-1} \mathbb{1}_S(x).
\]

(13)

The normalization factor is given by the multinomial beta function, which can be defined through the gamma function,

\[
B(a) = \frac{\prod_{i=1}^{n} \Gamma(a_i)}{\Gamma(\sum_{i=1}^{n} a_i)}.
\]

(14)

In the symmetric Dirichlet distribution all elements of the parameter vector \(a\) have the same value \(a_i = a\),

\[
f^D_D(x; a) = \frac{\Gamma(na)}{\Gamma(a)^n} \prod_{i=1}^{n} x_i^{n-1} \mathbb{1}_S(x).
\]

(15)

Notice that \(a = 1\) gives the uniform distribution on \(S\).

It is convenient to work with adimensional variables. With the rescaling \(u_{i\alpha} = \sqrt{m/(2E)} v_{i\alpha}\) introduced above, one gets the PDF

\[
f_u(x) = \frac{\Gamma(dN/2)}{2\pi^{dN/2}} \mathbb{1}_{\{x \in S\}}(x).
\]

A second transformation

\[
w_{i\alpha} = u_{i\alpha}^2
\]

leads to a set of \(dN\) random variables each one with support in \([0,1]\) and such that

\[
\sum_{i=1}^{n} \sum_{\alpha=1}^{d} w_{i\alpha} = 1.
\]

(18)

The Jacobian for this transformation is

\[
\frac{\partial u}{\partial w} = \frac{1}{2dN} \prod_{i=1}^{dN} \prod_{\alpha=1}^{d} w_{i\alpha}^{-1/2}.
\]

(19)

Multiplying it by a factor \(2^{dN}\) because each \(\pm u_{i\alpha}\) results in the same \(w_{i\alpha}\) and by another factor 2 because of the constraint given by Eq. (18) (for details see Song and Gupta \[24\]), and replacing \(\sqrt{\pi} = \Gamma(1/2)\), the joint PDF of the variables \(w_{i\alpha}\) can be expressed through the symmetric Dirichlet PDF with parameter \(a = 1/2\),

\[
f_w(x) = \frac{f^D_D(x; 1/2)}{\Gamma(1/2)^n} \prod_{i=1}^{n} x_i^{-1/2} \mathbb{1}_S(x).
\]

(20)

Now the normalized energy per particle,

\[
\varepsilon_i = \frac{E_i}{E} = \frac{m v_{i\alpha}^2}{2E} = \sum_{\alpha=1}^{d} w_{i\alpha},
\]

(21)

is the sum of \(d\) variables following the distribution given by Eq. (20). As a consequence of the aggregation law for Dirichlet distributions, one finds that the joint PDF of all \(\varepsilon_i\) is

\[
f_{\varepsilon}(x) = \frac{f^D_D(x; d/2)}{\Gamma(d/2)^n} \prod_{i=1}^{n} x_i^{d/2-1} \mathbb{1}_S(x).
\]

(22)
It is interesting to notice that this is a uniform distribution for $d = 2$; because of this, Boltzmann’s 1868 method works in $d = 2$ dimensions, but fails in $d = 3$ dimensions [10].

The PDF of the normalized energies of single particles can be obtained by a further marginalization of the symmetric Dirichlet distribution given by Eq. (22), using again the aggregation law. The result is a beta distribution, whose PDF is

$$f_X(x; a, b) = \frac{1}{\Gamma(b)} x^{a-1} (1-x)^{b-1} 1_{[0,1]}(x); \quad (23)$$

recalling Eq. (12), $B(a, b) = \Gamma(a) \Gamma(b) / \Gamma(a+b)$. Our case has the exponents $a = d/2$ and $b = d(N-1)/2$,

$$f_{E_i}(x) = f_{E_i}^\beta \left( x; \frac{d}{2}, \frac{d(N-1)}{2} \right) = \frac{\Gamma(dN/2)}{\Gamma(d/2) \Gamma(d(N-1)/2)} x^{d/2-1} \times (1-x)^{(dN-1)/2-1} 1_{[0,1]}(x).$$

The transformation of variables $E_i = E_{E_i}$ immediately leads to the PDF of particle energies, that follow a beta-Stacy distribution,

$$f_{E_i}(x) = f_{E_i}^\beta \left( \frac{x}{E}, \frac{d}{2}, \frac{d(N-1)}{2} \right) \frac{d}{dx} x \frac{\Gamma(dN/2)}{\Gamma(d/2) \Gamma(d(N-1)/2)} x^{d/2} \times (1-x)^{d(N-1)/2-1} 1_{[0,E]}(x) \quad (25)$$

for $N > 1$, and $f_{E_i}(x) = \delta(x - E)$ for $N = 1$. This result was obtained with a different method, without invoking the Dirichlet and beta distributions, by Shirts et al. [20, Eq. (9)].

In the thermodynamic limit $(N, V, E \to \infty$ with $N/V = \rho = \text{constant}$ and $E/N = \bar{E} = \text{constant}$), Eq. (25) converges to a gamma distribution, as discussed by Garibaldi and Scalas [24, pages 121–122]. The gamma PDF is

$$f_X(x; a, b) = \frac{x^{a-1} \exp(-x/b)}{b \Gamma(a)} 1_{[0,\infty)}(x).$$

A scale parameter is usually included in the definition of the gamma distribution, but it could always be set to 1 absorbing it into the argument,

$$f_X(x; a, b) = f_X^\gamma \left( x; \frac{a}{b}, 1 \right) \frac{1}{b} = f_X^\gamma \left( \frac{x}{b}; a \right) \frac{1}{b}. \quad (27)$$

Coming back to the thermodynamic limit of Eq. (25) anticipated above, this is a gamma distribution with shape parameter $a = d/2$ and scale parameter $b = 2\bar{E}/(dm)$,

$$f_{E_i}(x) = f_{E_i}^\gamma \left( x; \frac{d}{2}, \frac{2\bar{E}}{(dm)} \right) \frac{d^2}{dx^2} \frac{x^{d/2-1} \exp(-x/2\bar{E})}{\Gamma(d/2) 2\bar{E}} 1_{[0,\infty)}(x),$$

which is the familiar Boltzmann or Boltzmann-Gibbs distribution for $d = 2$.

The PDF of the velocity moduli, or speeds, of individual particles can be obtained from $f_{E_i}(x)$ replacing $v_i = \sqrt{2E_i/m}$. The result is a transformed beta-Stacy distribution with the same exponents $a = d/2$ and $b = d(N-1)/2$ as for the energies, but argument $mx^2/(2E)$,

$$f_{v_i}(x) = f_{v_i}^\beta \left( \frac{mx^2 \frac{d}{2} \frac{d(N-1)}{2}}{2 \bar{E}} \right) \frac{d}{dx} \frac{mx^2}{2\bar{E}} \times \frac{\Gamma(dN/2)}{\Gamma(d/2) \Gamma(d(N-1)/2)} \left( \frac{mx^2}{2\bar{E}} \right)^{\frac{d}{2}-1} \times \left( 1 - \frac{mx^2}{2\bar{E}} \right)^{\frac{d(N-1)}{2}-1} 1_{[0,\sqrt{2\bar{E}/m}]}(x) \quad (29)$$

for $N > 1$, and $f_{v_i}(x) = \delta(x - \sqrt{2\bar{E}/m})$ for $N = 1$. Also this result was obtained with a different method by Shirts et al. [20].

In the thermodynamic limit, Eq. (29) converges to the transformed gamma distribution with argument $x^2/2$, shape parameter $a = d/2$ and scale parameter $b = 2\bar{E}/(dm)$,

$$f_{v_i}(x) = f_{v_i}^\gamma \left( \frac{x^2 \frac{d}{2} \frac{2\bar{E}}{(dm)}}{dm} \right) \frac{d}{dx} \frac{x^2}{2} \times \frac{\Gamma(dN/2)}{\Gamma(d/2) \Gamma(d(N-1)/2)} \left( \frac{mx^2}{dm \bar{E}} \right)^{\frac{d}{2}-1} \exp(-\frac{dmx^2}{4\bar{E}}) 1_{[0,\infty)}(x) \quad (30)$$

which is the familiar Maxwell distribution for $d = 3$.

The transformation from hyperspherical coordinates to cartesian coordinates $v_i^2 = \sum_{\alpha=1}^d v_i^\alpha$ and

$$(2\pi)^{d/2} \Gamma(d/2)) v_i^{d-1} dv_i = \int_0^\infty \frac{d(N-1)}{2} \bar{E} \frac{dx}{(dx/2\bar{E})^{d-1}} \frac{1}{\Gamma(d/2)} \exp(-\frac{dmx^2}{4\bar{E}}) 1_{[0,\infty)}(x), \quad (31)$$

an equation obtained before too [20, 27].

The direct marginalization [25] of the joint PDF of all velocities, Eq. (10), leads to the PDF $f_{v_i}(x)$ of velocity components, a result obtained integrating over all $i$ except one and over all $\alpha$ except one. This is the quantity discussed by Maxwell [1], and its derivation for any $N$ is one of the main results in this paper. It turns out that the PDF of the velocity components is a transformed beta distribution with argument $1 + \sqrt{m_i/(2\bar{E})} x/2$ and
equal exponents $a = b = (dN - 1)/2$,

$$f_{\bar{v}_i}(x) = \frac{1}{2} \sqrt{\frac{m}{2E}} B((dN - 1)/2, (dN - 1)/2)$$

$$\times \left[ \frac{1}{2} + \sqrt{\frac{m x}{2E}} \left( \frac{1}{2} - \sqrt{\frac{m x}{2E}} \right) \right]^{(dN - 3)/2}$$

$$= \frac{1}{2^{dN-2}} \sqrt{\frac{m}{2E}} \frac{\Gamma(dN - 1)}{\Gamma^2((dN - 1)/2)}$$

$$\times \left( 1 - \frac{mx^2}{2E} \right)^{(dN - 3)/2} \frac{1}{\sqrt{\frac{m}{2E}}} (x)$$

$$= f^\beta_{\bar{v}_i} \left( \frac{1}{2} + \sqrt{\frac{m x}{2E}} \frac{dN - 1}{2}, \frac{dN - 1}{2} \right)$$

$$\times \frac{d}{dx} \left( \frac{1}{2} + \sqrt{\frac{m x}{2E}} \right). \tag{32}$$

In the thermodynamic limit Eq. (32) converges to a normal law with average $\mu = 0$ and variance $\sigma^2 = dE/(2m)$, i.e. the familiar Maxwell-Bozctmann distribution

$$f_{\bar{v}_i}(x) = \sqrt{\frac{m}{d\pi E}} \exp \left( -\frac{m x^2}{dE} \right). \tag{33}$$

This is again related to a gamma distribution, since the positive half of the normal distribution can be expressed as

$$\frac{2}{\sqrt{2\pi\sigma}} \exp \left( -\frac{x^2}{2\sigma^2} \right) 1_{[0,\infty)}(x) = f^\beta_X \left( \frac{x^2}{2}, \frac{1}{\frac{1}{2}}, \sigma^2 \right) \frac{d}{dx} \frac{x^2}{2}. \tag{34}$$

In summary, all the known results for the relevant distributions of the $NVE$ ensemble can be obtained observing that the normalized individual particle energies $\varepsilon_i = E_i/E$ follow a symmetric multivariate Dirichlet distribution with parameter $a = 1/2$ given by Eq. (20). This is a direct consequence of the uniform-distribution assumption in Eq. (3) via a simple change of variables. Only for the velocity components it is necessary to marginalize the uniform distribution directly on the surface of the hyper-sphere and not on the simplex. Maxwell’s Ansatz is vindicated by the fact that, in the thermodynamic limit, a normal distribution for velocity components is recovered, as well as their independence. Finally, for the $NV\bar{E}\bar{P}G$ ensemble, the constraint given in Eq. (35) leads to different distributions for the relevant quantities introduced above. This will become clearer in the following.

### III. MOLECULAR DYNAMICS SIMULATIONS

In molecular dynamics (MD) with continuous potentials, the equations of motion are integrated numerically using a constant time step; this approach is called time-driven. The larger the forces, the smaller the time step necessary to ensure energy conservation. With step potentials there are no forces acting on a distance, only impulsive ones at the exact time of impact. Therefore an event-driven approach is more appropriate: rather than until a fixed time step, the system is propagated until either the next collision or the next boundary crossing.

The collision time $t_{ij}$ between two particles $i,j$ can be calculated from the mutual distance $r_{ij} = \mathbf{r}_i - \mathbf{r}_j$ and the relative velocity $\mathbf{v}_{ij} = \mathbf{v}_i - \mathbf{v}_j$. If $b_{ij} = \mathbf{v}_{ij} \cdot r_{ij} > 0$ the particles are moving away from each other and will not collide. Otherwise impact may happen at time $t_{ij}$ when their distance becomes equal to the sum of their radii, i.e., $||\mathbf{r}_{ij} + t_{ij}\mathbf{v}_{ij}|| = \sigma$. This is a second order problem with solutions

$$t^\pm_{ij} = -\frac{b_{ij} \pm \sqrt{b_{ij}^2 - v_{ij}^2 (\sigma^2 - v_{ij}^2)}}{v_{ij}^2} \tag{35}$$

If the solutions are complex, no collision occurs. If the solutions are real, the smaller one, $t^-_{ij}$, corresponds to when the particles first meet, while the larger one, $t^+_{ij}$, to when they leave each other assuming they are allowed to interpenetrate. A negative collision time means that the event took place in the past. Because of the condition $b_{ij} < 0$, at least $t^+_{ij} > 0$. If $t^-_{ij} < 0$ the particles overlap, which indicates an error. So the collision time is given by $t^+_{ij}$, provided it is a positive real number.

For a system of $N$ hard spheres, at impact, assuming an elastic collision, the total kinetic energy $E$ and the total linear momentum $\mathbf{P}$ are conserved (usually one sets $\mathbf{P} = 0$ at the beginning of the simulation by subtracting $\sum_{i=1}^N \mathbf{v}_i$ from each $\mathbf{v}_i$). Assuming smooth surfaces, the impulse acts along the line of centers of the collision partners $i$ and $j$ given by $\mathbf{r}_{ij}$; with equal masses, $\mathbf{v}_i$ changes to $\mathbf{v}_i + \Delta \mathbf{v}_i$ and $\mathbf{v}_j$ changes to $\mathbf{v}_j - \Delta \mathbf{v}_j$ with

$$\Delta \mathbf{v}_i = -\frac{b_{ij} \mathbf{r}_{ij}}{\sigma^2} = -\frac{b_{ij} \mathbf{r}_{ij}}{\mathbf{v}_{ij} \cdot \mathbf{r}_{ij}} = -\mathbf{v}_{ij}, \tag{36}$$

where $\mathbf{r}_{ij}$ and $\mathbf{v}_{ij}$ are evaluated at the instant of collision, and thus $||\mathbf{r}_{ij}|| = \sigma$.

When a particle reaches a side of the unit box, periodic boundary conditions may require to “rebox” it by reintroducing it on the other side, while hard reflecting walls require to invert the velocity component perpendicular to the wall. After an event, be it a collision with another particle, a boundary crossing or a reflection at a boundary, the event calendar must be re-evaluated for pairs involving one of the event participants or a particle scheduled to collide with one of the event participants. All other particles are not influenced. Thus not every scheduled event actually takes place, because it can be invalidated by another earlier event, in which case it is erased from the priority queue. The latter is most commonly handled by means of a binary tree, which we realized with a multimap of the C++ Standard Template Library. The efficiency of this and alternative data structures for event scheduling has been analyzed extensively.

The computational effort to search for $\min_{i,j} t_{ij}$ grows as the square of the number of particles. For large systems it is advisable to divide the simulation box into
IV. MONTE CARLO SIMULATIONS

Except for especially ordered initial conditions, interparticle collisions computed by MD as explained in Sec. IIII have mutual distance versors at collision \( \hat{r}_{ij} \) uniformly distributed on a unit half sphere in \( d \) dimensions such that, given relative velocities \( v_{ij} \), the scalar product \( v_{ij} \cdot \hat{r}_{ij} \) is negative. Therefore the same distributions of velocities, and thus of derived quantities like energies, as in MD with periodic boundaries can be obtained by Monte Carlo (MC); after initializing the velocities of all hard spheres, the MC cycles consist in selecting a pair \( ij \) and a random versor \( \hat{r}_{ij} \) such that \( v_{ij} \cdot \hat{r}_{ij} < 0 \), and then in updating the velocities according to Eq. (39). Hard reflecting walls can be included in the MC scheme by selecting with a certain frequency a sphere \( i \) and inverting one of its velocity components \( v_{i\alpha} \). Altogether this is very much easier to code and faster to run, especially for large numbers of particles \( N \), than with MD, because no event list management is necessary. Moreover this scheme gives a useful insight into the mechanism of energy and momentum transfer.

For a given initial state (a set of particle velocities), the MC dynamics defined above provides the realization of a Markov chain with symmetric transition kernel, meaning that \( P(v'|v) = P(v|v') \), where \( v \) is the old velocity vector before the transition and \( v' \) is the new velocity vector after the transition. This Markov chain is homogeneous, as the transition probability does not depend on the time step. Invoking detailed balance, \( P(v'|v)P(v) = P(v|v')P(v') \), the symmetry of the transition kernel implies that the stationary distribution of this chain is uniform over the set of accessible states. If this set coincides with the surface of the velocity hypersphere, then the Markov chain is ergodic and one can hope to prove that the uniform distribution over the hypersphere is also the equilibrium distribution for the Markov chain; see Sigurgeirsson [42, Chapter 5] for the discussion of a related problem, and Meyn and Tweedie [43] for general methods. The results of MC simulations described below corroborate this conjecture and the algorithm outlined above is indeed an effective way of sampling the uniform distribution on the surface of a hypersphere.

V. NUMERICAL RESULTS

In Sec. IV we have presented a simple stochastic model able to reproduce the same empirical equilibrium distribution for the random variables \( v_{i\alpha} \) as obtained by MD simulations. In this sense, in principle, the above stochastic model and the related MC simulations can be used to estimate \( f_{v_{i\alpha}}(x) = \lim_{t \to \infty} f_{v_{i\alpha}}(x,t) \). It turns out that the PDF \( f_{v_{i\alpha}}(x) \) for \( d = 2 \) and \( N = 2 \) is fitted by the arcsine law,

\[
f_{v_{i\alpha}}(x) = \frac{1}{\pi \sqrt{2E/m - x^2}}.
\]

The name is due to its cumulative distribution function,

\[
F_{v_{i\alpha}}(x) = \frac{1}{\pi} \arcsin \left( \sqrt{\frac{m}{2E}x} \right) + \frac{1}{2}.
\]

If a Kolmogorov-Smirnov (KS) goodness-of-fit test [44–46] is performed comparing Eq. (38) with the empirical cumulative distribution function of MC velocities for \( N = 2 \), see Tab. I, one gets that the null hypothesis of arcsine-distributed data cannot be rejected at the 5% significance level. For our sample size the value of the KS statistic is \( 3.2 \times 10^{-4} \) with a p value of 0.99, the critical value being \( 9.6 \times 10^{-4} \). This test has not been repeated for MD velocities because the two empirical PDFs coincide as shown in Fig. 2.

For \( d = 2 \) and \( N = 3 \), \( f_{v_{i\alpha}}(x) \) is described by the semicircle law,

\[
f_{v_{i\alpha}}(x) = \frac{m}{2\pi E} \sqrt{\frac{4E}{m} - x^2}.
\]

Its cumulative distribution function again contains an arcsine,

\[
F_{v_{i\alpha}}(x) = \frac{mx}{4\pi E} \sqrt{\frac{m}{4E} - x^2} + \frac{1}{\pi} \arcsin \left( \sqrt{\frac{m}{4E}x} \right) + \frac{1}{2}.
\]

If a KS goodness-of-fit test is performed comparing Eq. (40) with the empirical cumulative distribution function of MC velocities for \( N = 3 \), one gets that the null
hypothesis of semicircle-distributed data cannot be rejected at the 5% significance level. For our sample size the value of the KS statistic is $6.0 \times 10^{-4}$ with a $p$ value of 0.46, the critical value being $9.6 \times 10^{-4}$. This test has not been repeated for MD velocities because the two empirical PDFs coincide as shown in Fig. 2.

For $d = 3$ and $N = 2$, $f_{v_{\text{vis}}}(x)$ is a uniform distribution on $[-\sqrt{2}, \sqrt{2}]$.

The arcsine distribution ($d = 2$, $N = 2$) is given by Eq. (32) with $a = 1/2$; the semicircle distribution ($d = 2$, $N = 3$) is given by $a = 3/2$; the case with $d = 2$, $N = 4$ is given by $a = 5/2$; the uniform distribution ($d = 3$, $N = 2$) is given by $a = 1$; the case with $d = 3$, $N = 3$ is given by $a = 5/2$; and so on.

The empirical density $f_{v_{\text{vis}}}(x)$ is well approximated by a normal law already for $N = 1000$ hard disks, as shown in Tab. III where the results of two non-parametric tests for normality, Lilliefors [47] and Jarque and Bera [48, 49], are presented when $N = 10, 100, 1000, 10000$; again these tests are done only for MC velocities.

FIG. 1: (Color online) Probability density functions of the velocity components (top), the velocity modulus (middle) and the energy (bottom) for $d = 2$ (left) and $d = 3$ (right) with $\bar{E} = 1$, hard reflecting walls and zero total momentum. Lines: theory; empty symbols: MD; full symbols: MC. Delta functions are made visible by a vertical line for the theory and by rescaling down to 1 the data point that would otherwise be out of scale.
FIG. 2: (Color online) Probability density functions of the velocity components (top), the velocity modulus (middle) and the energy (bottom) for $d = 2$ (left) and $d = 3$ (right) with $\bar{E} = 1$, periodic boundary conditions and zero total momentum. Lines: theory; empty symbols: MD; full symbols: MC. Notice that the velocity components and energy MD data for $N = 3$ deviate slightly from the theory and the MC data. Delta functions are made visible by a vertical line for the theory and by rescaling down to 1 the data point that would otherwise be out of scale.

VI. DISCUSSION AND CONCLUSIONS

To summarize what we have done, in a system of $N$ hard balls in a $d$-dimensional volume $V$ the velocity components, the velocity modulus and the energies of the spheres or disks are well reproduced by transformed beta distributions with different arguments and shape parameters depending on $N$, $d$, the total energy $E$, and the boundary conditions; in the thermodynamic limit these distributions converge to transformed gamma distributions with different arguments and shape or scale parameters, corresponding respectively to the Gaussian, i.e. Maxwell-Boltzmann, the Maxwell, and the Boltzmann or Boltzmann-Gibbs distribution. We showed this theoretically using Khinchin’s Ansatz, and performed statistical goodness-of-fit tests on systematic MD and MC computer simulations of an increasing number $N$ of hard disks or spheres starting from 2 in the microcanonical
sis is known as the Boltzmann-Sinai ergodic hypothesis.

One should prove that every hard-ball system on a flat torus is fully hyperbolic and ergodic, after fixing its total energy, momentum, and center of mass. This rephrasing of Boltzmann’s hypothesis in full generality for hard ball systems is justiﬁed for systems of hard balls. We would like to stress that this is a consequence of the microscopic dynamics and not of any a priori maximum-entropy principle. The uniform distribution on the accessible phase-space region is indeed the maximum-entropy distribution. Therefore, maximum-entropy methods do work well and all the distributions in Sec. II could be obtained by maximum-entropy methods: the beta and gamma distributions are actually the maximum-entropy distributions with given ﬁrst moment, and possibly some other constraint, on a ﬁnite and a semi-inﬁnite interval respectively. However, this is so only because the dynamics uniformly samples the accessible phase-space region and not the other way round. In different frameworks, e.g. in biology or economics, maximum-entropy assumptions might lead to wrong results for the equilibrium distribution of a system, if its dynamics is not speciﬁed or carefully studied.

The distributions derived in Sec. II are a benchmark for random partition models popular in econophysics. Pure exchange models often lead to the same distributions 

| $N$ | Lilliefors | $p_L$ | Jarque-Bera | $p_{JB}$ |
|-----|---------|------|-------------|---------|
| 10  | 0.008*  | < 1  | 7.4 $\times$ 10^{-4} | < 1  |
| 100 | 7.36 $\times$ 10^{-4} | 0.01 | 29.6* | < 1  |
| 1000| 4.79 $\times$ 10^{-4}  | 0.35 | 5.70 | 0.06 |
| 10000| 4.37 $\times$ 10^{-4} | 0.50 | 2.36 | 0.31 |

TABLE II: Results of two non-parametric normality tests for the empirical probability density function of the velocity components from MC with periodic boundary conditions when $d = 2$: Lilliefors (L) and Jarque and Bera (JB). The sample size is $n = 2 \times 10^6$. At the 5% signiﬁcance level the critical value is $6.43 \times 10^{-4}$ for the L test and 5.99 for the JB test. The star indicates that the null hypothesis of normally distributed data can be rejected.

The MD simulations presented above corroborate Boltzmann’s ergodic hypothesis both for the $NVE$ and the $NVE_{PG}$ ensembles. The proofs of ergodicity for similar systems used the so-called Chernov-Sinai Ansatz, namely the almost sure hyperbolicity of singular orbits; hyperbolicity means a non-zero Lyapunov exponent almost everywhere with respect to the Liouville measure. It was Sinai who, earlier, had updated Boltzmann’s ergodic hypothesis. One should prove that every hard-ball system on a ﬂat torus is fully hyperbolic and ergodic, after ﬁxing its total energy, momentum, and center of mass. This rephrasing of Boltzmann’s hypothesis is known as the Boltzmann-Sinai ergodic hypothesis.

More recently, Simányi proved the Boltzmann-Sinai ergodic hypothesis in full generality for hard ball systems.

VII. ACKNOWLEDGMENTS

We are thankful to Ubald Garibaldi for pointing us to the Dirichlet distribution as the multivariate generalization of the beta distribution. We are thankful to Mauro Politi for observing that the beta distribution maximizes the entropy on a ﬁnite interval given some constraints that include the ﬁrst moment, even if we did not use this property in the theory exposed in Sec. II.
