ABSTRACT

We present $^{12}$CO($J = 1 \rightarrow 0$) observations of the high-redshift quasi-stellar objects (QSOs) BR 1202−0725 ($z = 4.69$), PSS J2322+1944 ($z = 4.12$), and APM 08279+5255 ($z = 3.91$) using the NRAO Green Bank Telescope (GBT) and the MPRF Effelsberg 100 m telescope. We detect, for the first time, the CO ground-level transition in BR 1202−0725. For PSS J2322+1944 and APM 08279+5255, our observations result in line fluxes that are consistent with previous NRAO Very Large Array (VLA) observations, but they reveal the full line profiles. We report a typical lensing-corrected velocity-integrated intrinsic $^{12}$CO($J = 1 \rightarrow 0$) line luminosity of $L^{12\text{CO}}_{\text{mol}} = 5 \times 10^{10}$ K km s$^{-1}$ pc$^{-2}$ and a typical total H$_2$ mass of $M(\text{H}_2) = 4 \times 10^{10} M_\odot$ for the sources in our sample. The CO/FIR luminosity ratios of these high-$z$ sources follow the same trend as seen for low-$z$ galaxies, leading to a combined solution of $L_{\text{FIR}}(1.39 \pm 0.05) \log L^{12\text{CO}}_{\text{mol}} - 1.76$. It has previously been suggested that the molecular gas reservoirs in some quasar host galaxies may exhibit luminous, extended $^{12}$CO($J = 1 \rightarrow 0$) components that are not observed in the higher $J$ CO transitions. Using the line profiles and the total intensities of our observations and large velocity gradient (LGV) models based on previous results for higher $J$ CO transitions, we derive that emission from all CO transitions is described well by a single gas component in which all molecular gas is concentrated in a compact nuclear region. Thus, our observations and models show no indication of a luminous extended, low surface brightness molecular gas component in any of the high-redshift QSOs in our sample. If such extended components exist, their contribution to the overall luminosity is limited to at most 30%.

1. INTRODUCTION

Understanding when and how galaxies form is one of the primary objectives in both observational and theoretical astrophysics. The mere fact that active galaxies, such as radio galaxies, quasi-stellar-objects (QSOs), and emission-line galaxies are observed up to redshifts of $z = 6.6$ (e.g., Fan et al. 2001; Rhoads & Malhotra 2001; Hu et al. 2002; Kodaira et al. 2003; Taniguchi et al. 2005), less than 1 Gyr after recombination, implies that the growth of large-scale structures since the epoch of recombination. The study of the masses and dynamical state of these young systems serves as a direct constraint to the models at this early epoch. The detection of carbon monoxide (CO) is also a strong confirmation that star formation is going on in some of the highest redshift systems. In fact, the combination of molecular gas and dust detections with large far-infrared (FIR) luminosities provides the strongest evidence that a significant fraction of high-$z$ galaxies are undergoing starbursts at prodigous rates ($>10^3 M_\odot$ yr$^{-1}$), consistent with the formation of a large elliptical galaxy on a dynamical timescale of $\sim 10^7$−$10^8$ yr.

Over the past decade, more than 30 galaxies at $z > 2$ have been detected in CO emission (Solomon & Vanden Bout 2005) out to a redshift of $z = 6.42$ (Walter et al. 2003, 2004; Bertoldi et al. 2003), confirming the presence of intense starbursts in numerous high-$z$ galaxies. As most of these observations were obtained using millimeter interferometers, these detections were typically achieved by observing high-$J$ CO($J \rightarrow J - 1$) transitions ($J \geq 3$). Although these high-$J$ lines exhibit in general higher peak flux densities than the ground-state ($J = 1$) transition, it is possible that the higher order transitions are biased to the excited gas close to a central starburst and do not necessarily trace the entire molecular gas reservoir seen in $^{12}$CO($J = 1 \rightarrow 0$). In addition, the conversion factor ($\alpha$) to derive molecular (H$_2$) masses from measured CO luminosities has mostly been estimated for the $^{12}$CO($J = 1 \rightarrow 0$) line (e.g., Downes & Solomon 1998; Weiss et al. 2001). Observing $^{12}$CO($J = 1 \rightarrow 0$) has the additional advantage that properties of the highly redshifted sources...
can be directly compared to the molecular gas properties of nearby (starburst) galaxies that are predominantly mapped in the $^{12}\text{CO}(J = 1 \rightarrow 0)$ transition.

These are main motivations for observing the $^{12}\text{CO}(J = 1 \rightarrow 0)$ ground-state transition. However, due to the faintness of the line and the bandwidth limitations of current radio telescopes, such high-$z$ $^{12}\text{CO}(J = 1 \rightarrow 0)$ observations only exist for two QSOs and two radio galaxies to date. All of these observations have been obtained with radio interferometers operating at centimeter wavelengths: the NRAO Very Large Array (VLA; Papadopoulos et al. 2001; Carilli et al. 2002a; Greve et al. 2004) and the Australia Telescope Compact Array (ATCA; Klammer et al. 2005). In particular, due to the bandwidth limitations of the VLA, obtaining better constraints on the spectral line shape and total flux of the $^{12}\text{CO}(J = 1 \rightarrow 0)$ transition is desirable even for already detected sources. Today’s largest single-dish telescopes, such as the NRAO Green Bank Telescope (GBT)\(^{10}\) and the MPIfR Effelsberg telescope,\(^{11}\) can eliminate some of those issues due to their larger spectral bandwidths.

Here we report on first observations of $^{12}\text{CO}(J = 1 \rightarrow 0)$ in three CO-bright high-$z$ QSOs, which also exhibit ultraluminous IR emission, using the GBT and the Effelsberg telescope. In § 2, we describe our observations. Section 3 summarizes our results on the individual objects (BR 1202--0725 at $z = 4.69$, PSS J2322+1944 at $z = 4.12$, and APM 08279+5255 at $z = 3.91$). Section 4 provides an analysis and discussion, and § 5 closes with a summary of our results. We assume a standard $\Lambda$CDM cosmology throughout, with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_{\text{m}} = 0.27$, and $\Omega_{\Lambda} = 0.73$ (Spergel et al. 2003).

2. OBSERVATIONS

2.1. Green Bank Telescope

Observations of the three targets were carried out with the GBT during 12 observing runs between 2004 October and 2005 April with a total observing time of 89.5 hr. The total on-source observing times were 31.5/20 hr for BR 1202--0725, 23/15 hr for PSS J2322+1944, and 35/22 hr for APM 08279+5255. During all runs, 3C 147 and 3C 286 were used as primary/flux calibrators. For spectral line calibration, we observed IRC +10216, 3C 147, and 3C 286 during all runs, 3C 147 and 3C 286 were used as primary/flux calibrators. For PSS J2322+1944, and 35/22 hr for APM 08279+5255. During all runs, 3C 147 and 3C 286 were used as primary/flux calibrators. For spectral line calibration, we observed IRC +10216, 3C 147, and 3C 286 during all runs, 3C 147 and 3C 286 were used as primary/flux calibrators. For PSS J2322+1944, and 35/22 hr for APM 08279+5255. During all runs, 3C 147 and 3C 286 were used as primary/flux calibrators.

2.2. Effelsberg Telescope

Observations were carried out toward BR 1202--0725 and PSS J2322+1944 in 2003 January and February with a total observing time of $\sim 50$ hr (20 hr per source, corresponding to 8 hr on-source each). At 40’’ beam size, the pointing accuracy, as determined by continuum cross scans of nearby sources, was better than 10’’, with typical values of $\sim 5$”.

---

10 The Green Bank Telescope is a facility of the National Radio Astronomy Observatory (NRAO), operated by Associated Universities, Inc., under a cooperative agreement with the National Science Foundation.
11 The Effelsberg telescope is a facility of the Max-Planck-Gesellschaft (MPG), operated by the Max-Planck-Institut für Radioastronomie (MPIfR).

total formal calibration uncertainty of ~15%. We observed in beam switching mode using a rotating horn with a beam throw of 2° and a switching frequency of ~1 Hz. We have used a dual polarization HEMT receiver for all observations. The autocorrelator backend was split into eight bands of 160 MHz bandwidth and 128 channels each that could individually be shifted in frequency by up to ±250 MHz relative to the recessional velocity of the targets. The final spectra cover a velocity range of ~6000 km s⁻¹ with channel spacings of ~16 km s⁻¹. We achieved single channel system temperatures of 65 and 85 K on a Tsys scale. After combination of both orthogonal linear polarizations, this leads to Tsys of 47 and 60 K.

The GILDAS/CLASS package was used for data reduction. All spectral baselines are of good quality and only first-order polynomial baselines had to be subtracted. The final spectra of BR 1202−0725 and PSS J2322+1944 are shown in the middle panels of Figures 1 and 2. These spectra were binned to 5.97 MHz (88 km s⁻¹) and 3.60 MHz (48 km s⁻¹), reaching rms noise values of ~150 and ~380 μJy, respectively. We note that the latter do not show the full ranges used for spectral baseline fitting. Those ranges (~380 MHz for BR 1202−0725 and ~180 MHz for PSS J2322+1944) are illustrated by the insets in the same figures.

2.3. Combined Spectra

As BR 1202−0725 and PSS J2322+1944 were observed with both telescopes, we also created combined spectra of both results to increase the signal-to-noise ratio and average out part of the calibrational uncertainties. The GILDAS/CLASS package was
used to reprocess and combine the final spectra of both telescopes. The final unbinned GBT and Effelsberg spectra were regridded to a common velocity resolution and baseline-subtracted before combination. In the combination, spectra were weighted with their respective rms. The combined spectra of BR 1202–0725 and PSS J2322+1944, as shown in the bottom panels of Figures 1 and 2, were binned to a resolution of 2.00 MHz (30 km s\(^{-1}\)) and 1.80 MHz (24 km s\(^{-1}\)), reaching rms noise values of \(\sim70\) and \(\sim125\) \(\mu\)Jy, respectively.

3. RESULTS
The sources in our study are the three CO-brightest high-redshift QSOs that can currently be observed in the \(^{12}\)CO(1–0) transition. We obtained detections for all our targets. CO line luminosities \(L'_{\text{CO}}\) (in K km s\(^{-1}\) pc\(^2\)) were derived using

\[
L'_{\text{CO}} = 3.25 \times 10^7 \left[ I_{\text{obs}} D_L^2 (1 + z)^{-3} \right],
\]

where \(I\) is the velocity-integrated \(^{12}\)CO(1–0) line flux in Jy km s\(^{-1}\), \(D_L\) is the luminosity distance in Mpc, and \(v_{\text{obs}}\) is the observed frequency in GHz (Solomon et al. 1992). For the systems with known lensing magnification factor \(\mu_{\text{L}}\), \(L'_{\text{CO}}\) has to be divided by that factor in order to get the intrinsic CO luminosity of the discussed target. A conversion factor \(\alpha = 0.8 \, M_\odot \, \text{K}^{-1} \, \text{km} \, \text{s}^{-1} \, \text{pc}^2\) to convert \(L'_{\text{CO}(1-0)}\) to \(M_{\text{gas}}(\text{H}_2)\) is assumed throughout, as applicable for local ultraluminous infrared galaxies (ULIRGs)/starbursts (Downes & Solomon 1998). All observational results are summarized in Table 1. Derived CO luminosities and gas masses as well as FIR luminosities from the literature are given in Table 2.

3.1. BR 1202–0725

3.1.1. Previous Results

BR 1202–0725 (\(z = 4.69\)) was detected in multiple CO transitions before (see Table 3) but not in \(^{12}\)CO(1–0). This optically bright, radio-quiet QSO has the curious property that the optical QSO is a single source, but the millimeter continuum and CO line observations show a double source with a separation of about 4\(\arcsec\) (Onmont et al. 1996; Guilloteau et al. 1999; Carilli et al. 2002b). This double morphology may indicate a pair of interacting objects separated by only 28 kpc (Yun et al. 2000; Carilli et al. 2002b). An alternative explanation would be a double-starburst system composed of a QSO ( southern source) and a dust-obscured, Ly\(-\)emitting companion (northern source; Hu et al. 1996), which is ionized by the strong QSO. Recently, Klaer et al. (2004) suggested that the nature of the double source might be due to jet-induced star formation, in which the northern component corresponds to a radio hot spot. It has been discussed that the quasar activity in this system may be triggered by gravitational interaction with the companion. Using typical conversion factors for a ULIRG (Downes & Solomon 1998), the total molecular gas mass derived from the CO luminosity exceeds the dynamical mass of the system (Carilli et al. 2002b), and as a remedy for this inconsistency, gravitational lensing has been suggested. However, the same authors argue that masses and velocity widths of the components are very different; therefore, it appears unlikely that the multiple components are different lensed images of one source.

3.1.2. New Observations

The final \(^{12}\)CO(1–0) spectra of BR 1202–0725 are shown in Figure 1 (top, GBT; middle, Effelsberg; bottom, combined spectrum). Gaussian fitting to the line profile of the combined spectrum results in a peak flux density of 0.34 \(\pm\) 0.03 mJy and a FWHM of 333 \(\pm\) 30 km s\(^{-1}\). The integrated \(^{12}\)CO(1–0) line flux is 0.120 \(\pm\) 0.010 Jy km s\(^{-1}\). This agrees well

---

**Table 1**

| Source | \(z\) | \(v_{\text{obs}}\) (GHz) | \(S'_{\text{v}}\) (mJy) | \(\Delta V_{\text{FWHM}}\) (km s\(^{-1}\)) | \(I\) (Jy km s\(^{-1}\)) | Telescope |
| --- | --- | --- | --- | --- | --- | --- |
| BR 1202–0725 | 4.6932 \(\pm\) 0.0004 | 20.2450 | 0.36 \(\pm\) 0.03 | 329 \(\pm\) 36 | 0.124 \(\pm\) 0.012 | GBT |
| | 4.6956 \(\pm\) 0.0002 | 20.2388 | 0.40 \(\pm\) 0.11 | 522 \(\pm\) 146 | 0.22 \(\pm\) 0.06 | Effelsberg |
| | 4.6949 \(\pm\) 0.0003 | 20.2411 | 0.34 \(\pm\) 0.03 | 333 \(\pm\) 30 | 0.120 \(\pm\) 0.010 | Combined |

| | 4.1184 \(\pm\) 0.0008 | 22.5211 | 1.29 \(\pm\) 0.26 | 184 \(\pm\) 46 | 0.25 \(\pm\) 0.06 | Effelsberg |
| | 4.1179 \(\pm\) 0.0002 | 22.5231 | 0.77 \(\pm\) 0.07 | 190 \(\pm\) 14 | 0.155 \(\pm\) 0.013 | Combined |
| APM 08279+5255 | 3.9122 \(\pm\) 0.0007 | 23.4663 | 0.26 \(\pm\) 0.04 | 556 \(\pm\) 55 | 0.152 \(\pm\) 0.020 | GBT |

**Notes.**—All given uncertainties are formal (correlated) errors from the Gaussian fit. The \(z\) error was derived from a full three-parameter fit. In the error estimates for \(S'_{\text{v}}\) and \(\Delta V_{\text{FWHM}}\), the correlation with the error in \(z\) is neglected, as the relative uncertainty in \(z\) is \(\sim3\) orders of magnitude less than that of the other two quantities. The error estimate for \(I\) takes the correlation of the errors of \(S'_{\text{v}}\) and \(\Delta V_{\text{FWHM}}\) into account.

\(^{a}\) A \(T'_{\text{A}}(\text{K})/S'(\text{Jy})\) conversion factor of 1.5 was assumed for the GBT.
with the extrapolated value of $0.123 \pm 0.013$ Jy km s$^{-1}$ derived from the $^{12}$CO($J = 2 \rightarrow 1$) flux (Carilli et al. 2002b) under assumption of fully thermalized and optically thick CO emission (see also discussion in § 4.1). The width of the $^{12}$CO($J = 1 \rightarrow 0$) line is consistent within the error bars with an average of the higher $J$ transitions in the literature ($\sim 290$ km s$^{-1}$; see Table 3). The derived redshift of 4.6949 ± 0.0003 is in good agreement with the $^{12}$CO($J = 5 \rightarrow 4$) redshift (Omont et al. 1996; northern and southern components combined). The structure of this source is unresolved at the resolution of our measurements; all line parameters in Table 3 are in good agreement with the higher $J$ lines adding up both components. The derived CO line luminosity of $1.0 \times 10^{11}$ K km s$^{-1}$ pc$^2$ results in an H$_2$ gas mass of $8.1 \times 10^{10}$ $M_\odot$ (see also Table 2).

### Table 2: Luminosities, Gas Masses, and Star Formation Rates

3.2. PSS J2322+1944

3.2.1. Previous Results

The $z = 4.12$ QSO PSS J2322+1944 is an IR-luminous high-redshift source (see Table 2) that is known to exhibit strong CO line emission in multiple transitions (see Table 3). Optical imaging and spectroscopy reveal a double-source structure, and the two components are separated by about 15". The spectra of both peaks are essentially identical, consistent with strong gravitational lensing (optical magnification factor $\mu_\text{L}^\text{CO} = 3.5$) by an intervening foreground galaxy (Carilli et al. 2003). In high-resolution VLA images, Carilli et al. (2003) find a molecular Einstein ring with a diameter of 15" in $^{12}$CO($J = 2 \rightarrow 1$) line emission, which can be modeled as a circumnuclear star-forming disk with a radius of 2.2 kpc (CO magnification factor $\mu_\text{L}^\text{CO} \approx 2.5$). The derived intrinsic star formation rate (SFR) is of the order of 900 $M_\odot$ yr$^{-1}$. PSS J2322+1944 exhibits strong, nonthermal (synchrotron) radio continuum emission at 1.4 GHz, and the rest-frame radio-to-IR spectral energy distribution (SED) resembles that of local nuclear starburst galaxies such as M82 (Cox et al. 2002). This QSO is the fourth high-$z$ CO emitter to be detected in [C II] emission (Pety et al. 2004), providing additional evidence for the presence of active star formation in the host galaxy.

3.2.2. New Observations

The final $^{12}$CO($J = 1 \rightarrow 0$) spectra of PSS J2322+1944 are shown in Figure 2 (top, GBT; middle, Effelsberg; bottom, combined spectrum). From Gaussian fitting to the combined spectrum, the peak line flux density is found to be $0.77 \pm 0.07$ mJy, the line FWHM is $190 \pm 14$ km s$^{-1}$, and the integrated line flux is $0.155 \pm 0.013$ Jy km s$^{-1}$. These values are in good agreement with the $^{12}$CO($J = 1 \rightarrow 0$) detection of Carilli et al. (2002a; $S_\text{CO} = 0.89 \pm 0.22$ mJy, $\Delta V_{\text{FWHM}} = 200 \pm 70$ km s$^{-1}$, $J = 0.19 \pm 0.08$ Jy km s$^{-1}$), although results for the higher $J$ CO transitions indicate a larger line width ($\Delta V_{\text{FWHM}} > 250$ km s$^{-1}$; see Table 3). The Gaussian fit gives a redshift of 4.1179 $\pm 0.0002$. The derived lensing-corrected CO line luminosity of $4.2 \times 10^{10}$ K km s$^{-1}$ pc$^2$ results in an H$_2$ gas mass of $3.4 \times 10^{10} M_\odot$ (see also Table 2).

3.3. APM 0827+5255

3.3.1. Previous Results

APM 0827+5255 is a strongly lensed, radio-quiet broad absorption line (BAL) QSO at $z = 3.91$. Gravitational lens models of the QSO continuum source suggest magnification by a factor of $\mu_\text{L}^\text{CO} \sim 100$, and the image breaks up into three components with a maximum separation of 0.4 (Ledoux et al. 1998; Ibata et al. 1999; Egami et al. 2000). APM 0827+5255 has been detected in the millimeter and submillimeter dust continuum, revealing an apparent bolometric luminosity of $\sim 5 \times 10^{15} L_\odot$ (Lewis et al. 1998). A multitransition CO study (see Table 3) in combination with detailed lens models appears to reveal a spatially extended structure on a scale of at least 400 pc (Lewis et al. 2002), which is gravitationally magnified by a factor of $\mu_\text{L}^\text{CO} = 7$. The strength of the $^{12}$CO($J = 9 \rightarrow 8$) emission indicates the presence of high dense gas with a kinetic temperature of approximately 200 K (Downes et al. 1999).

From VLA imaging of the CO ground-state transition at a linear resolution of 27"25, Papadopoulos et al. (2001) report the detection of an extended, low-excitation molecular gas reservoir around the compact nucleus that extends over a scale of 7" ($\sim 30$ kpc). The integrated brightness temperature of this extended domain appears to be of the same order of magnitude as that of the nuclear region. This extended reservoir would be well

within our 32" GBT beam. Papadopoulos et al. (2001) do not derive the total flux in the extended reservoir. For the central $\sim 1"$ (corresponding to $\sim 7.2$ kpc at the source redshift), which they call "the nuclear $^{12}$CO($J = 1 \rightarrow 0$) emission," they find an integrated flux of $0.150 \pm 0.045$ Jy km s$^{-1}$. The VLA bandpass used by Papadopoulos et al. (2001) has an effective bandwidth of $\sim 45$ MHz, or $\sim 575$ km s$^{-1}$ at the $^{12}$CO($J = 1 \rightarrow 0$) line frequency. Therefore, assuming that the peak in their Figure 1c is $6.5 \sigma = 260 \mu$Jy beam$^{-1}$ ($\sigma = 40 \mu$Jy beam$^{-1}$), we consistently derive an integrated flux over the peak of 0.15 Jy km s$^{-1}$ beam$^{-1}$. However, Papadopoulos et al. (2001) suggest that this peak of "nuclear emission" sits on a broad, extended plateau (see their Fig. 1c). If we assume that the extended reservoir component is traced by their 2 $\sigma$ (80 $\mu$Jy beam$^{-1}$) contour, it has a width of $\sim 8" \times 3"$, or $\sim 4.7$ beam areas at the given resolution of 2725. This corresponds to a flux of $0.22$ Jy km s$^{-1}$ for the extended emission. The same estimate for their 3 $\sigma$ (120 $\mu$Jy beam$^{-1}$) contour gives a width of $\sim 7" \times 2"$, or $\sim 3.1$ beam areas. This again corresponds to a flux of $0.22$ Jy km s$^{-1}$ (note that both these estimates are lower limits for the extended emission).

The total flux in the $^{12}$CO($J = 1 \rightarrow 0$) map of Papadopoulos et al. (2001) is therefore estimated to be $\geq 0.37$ Jy km s$^{-1}$. The same authors also suggest that this reservoir breaks up into multiple components at higher resolution; in their $^{12}$CO($J = 2 \rightarrow 1$) observations at 0.5 resolution, they claim to find two emitting regions $2"-3"$ distant from the central region; if real, these could be companion galaxies that are not individually resolved in the extended $^{12}$CO($J = 1 \rightarrow 0$) reservoir.

3.3.2. New Observations

The final $^{12}$CO($J = 1 \rightarrow 0$) spectrum of APM 0827+5255 is shown in Figure 3. We derive a $^{12}$CO($J = 1 \rightarrow 0$) peak flux of $0.26 \pm 0.04$ mJy and a FWHM of $556 \pm 55$ km s$^{-1}$ from our Gaussian fit. This results in an integrated line flux of $0.152 \pm 0.020$ Jy km s$^{-1}$, which is in good agreement with the value of $0.150 \pm 0.045$ Jy km s$^{-1}$ found by Papadopoulos et al. (2001) for the central $\sim 1"$ ["the nuclear $^{12}$CO($J = 1 \rightarrow 0$) emission"]'). However, our result is inconsistent with the integrated flux of $0.37$ Jy km s$^{-1}$ given by our estimate of their full $^{12}$CO($J = 1 \rightarrow 0$) reservoir (see previous subsection). Such a high flux is clearly ruled out by our GBT observations. We thus find no evidence for a luminous extended halo, which would be well within our 32" beam, and cannot confirm the existence of bright companion galaxies. The derived FWHM velocity width of our $^{12}$CO($J = 1 \rightarrow 0$) detection is in agreement with single-dish observations of the $^{12}$CO($J = 6 \rightarrow 5$), $^{12}$CO($J = 10 \rightarrow 9$), and $^{12}$CO($J = 11 \rightarrow 10$) transitions obtained with the IRAM 30 m telescope ($\sim 500$ km s$^{-1}$; Weiss et al. 2006) and IRAM Plateau de Bure interferometer observations of the $^{12}$CO($J = 4 \rightarrow 3$) transition ($480 \pm 35$ km s$^{-1}$; Downes et al. 1999; see Table 3). Our derived $^{12}$CO($J = 1 \rightarrow 0$) redshift of $3.9122 \pm 0.0007$ is in good agreement with previous results ($3.9114 \pm 0.0003$ for the 4 transition). The derived lensing-corrected CO line luminosity of $1.4 \times 10^{10}$ K km s$^{-1}$ pc$^2$ results in an H$_2$ gas mass of $1.1 \times 10^{10} M_\odot$ (see also Table 2).

4. ANALYSIS AND DISCUSSION

4.1. Large Velocity Gradient Modeling

To investigate how much of the $^{12}$CO($J = 1 \rightarrow 0$) emission in our target QSOs is associated with the molecular gas reservoirs detected in the higher-J CO transitions, we have used spherical, one-component large velocity gradient (LVG) models. All these LVG calculations use the collision rates from Flower & Pineau des Forets...
Fig. 4.—CO ladder and LVG models (based on all $J > 1$ transitions) for BR 1202−0725. The inset shows a zoomed-in version of the $J = 2, 1$ region (as indicated by the dashed box). The filled triangle is the $^{12}$CO($J = 1 → 0$) data point based on the combined spectrum. Data for the higher $J$ CO transitions (open triangles) are taken from the literature (see Table 3). For comparison, we also show data for the inner disk of the Milky Way (open squares; Fixsen et al. 1999), normalized to the $^{12}$CO($J = 1 → 0$) flux of BR 1202−0725. The kinetic temperature $T_{\text{kin}}$ and gas density $n_{\text{gas}}(H_2)$ are treated as free parameters in this study. Three representative models are shown: Model 1 (solid line) assumes $T_{\text{kin}} = 60$ K and $n_{\text{gas}}(H_2) = 10^{4.1}$ cm$^{-3}$ and gives the overall best fit to all transitions. Model 2 (dashed line) assumes $T_{\text{kin}} = 120$ K and $n_{\text{gas}}(H_2) = 10^{3.7}$ cm$^{-3}$, while model 3 (dotted line) assumes $T_{\text{kin}} = 30$ K and $n_{\text{gas}}(H_2) = 10^{4.6}$ cm$^{-3}$.

(2001) with an ortho/para $H_2$ ratio of 3 and a CO abundance per velocity gradient of $[CO]/(\text{dv}/\text{dr}) = 1 \times 10^{-5}$ pc (km s$^{-1}$)$^{-1}$ (e.g., Weiss et al. 2005). Models were fitted to those lines above the $^{12}$CO($J = 1 → 0$) transition listed in Table 3 for each source. The turnover of the CO line SED (and therefore the slope beyond the turnover) is not well determined. Thus, a large degeneracy exists between the kinetic gas temperature $T_{\text{kin}}$ and density $n_{\text{gas}}(H_2)$, the two main free parameters in our study. As an example, Figure 4 shows data of all transitions and three representative models for BR 1202−0725: Model 1 (solid line) assumes $T_{\text{kin}} = 60$ K and $n_{\text{gas}}(H_2) = 10^{4.1}$ cm$^{-3}$ and gives the overall best fit to all transitions. Models 2 (dashed line) and 3 (dotted line) are shown as a representation of the parameter space allowed by the data within the error bars. Model 2 assumes $T_{\text{kin}} = 120$ K and $n_{\text{gas}}(H_2) = 10^{3.7}$ cm$^{-3}$, while model 3 assumes $T_{\text{kin}} = 30$ K and $n_{\text{gas}}(H_2) = 10^{4.6}$ cm$^{-3}$. The LGV predicted $^{12}$CO($J = 1 → 0$) flux of the different models based on the $J > 1$ CO transitions is fairly well constrained by the solutions. Most of our calculated models suggest that the CO emission is close to thermalized up to the $^{12}$CO($J = 4 → 3$) transition and optically thick ($\tau \geq 5$), which implies that the LGV predicted $^{12}$CO($J = 1 → 0$) line fluxes are similar to those we would derive by assuming a $\nu^2$ scaling of the line flux densities from the mid-J CO transitions. The predicted LGV integrated flux ranges of the $^{12}$CO($J = 1 → 0$) transition are $0.10−0.12$ Jy km s$^{-1}$ (BR 1202−0725), $0.20 − 0.23$ Jy km s$^{-1}$ (PSS J2322+1944), and $0.13−0.20$ Jy km s$^{-1}$ (APM 08279+5255) and are in good agreement with our observations for all sources. As described in § 3.2.2, the observed $^{12}$CO($J = 1 → 0$) line width in our new observations and in the VLA spectrum (Carilli et al. 2002a) of PSS J2322+1944 is lower than that of the higher $J$ transitions; thus, the integrated model fluxes are a bit higher than our result. If we compare the peak fluxes only, we obtain a good agreement.

Our observations and models are in agreement with the assertion that all observed $^{12}$CO($J = 1 → 0$) flux density is associated with the highly excited molecular gas seen in the high-J CO lines. We thus find no evidence for an additional luminous, more extended low surface brightness gas component surrounding the central region of our target QSOs, in contrast to what has been suggested previously for APM 08279+5255 (Papadopoulos et al. 2001). Given the accuracy of our measurements, we conclude that at most 20%–30% of the $^{12}$CO($J = 1 → 0$) luminosity may be associated with such a diffuse component. We note, however, that if the $L_{\text{CO}}^{12}$ to $M_{\text{gas}}(H_2)$ conversion factor ($\alpha$) for a faint extended component were higher (e.g., Galactic), a higher $H_2$ mass may be hidden in such an extended component.

4.2. Correlations of High- and Low-Redshift Galaxies

CO results for our three high-redshift IR-luminous QSOs are summarized in Tables 1 and 2. Our sample consists of all three high-$z$ QSOs for which the CO ground-state transition has been detected to date and covers $\sim 20\%$ of the CO-detected $z > 2$ quasars. As discussed above, the $^{12}$CO($J = 1 → 0$) transition provides the best information of the total amount of molecular gas in a system, quantified by $L_{\text{CO}}^{12}$. For most QSOs/galaxies detected in CO at high $z$, $^{12}$CO($J = 3 → 2$) and $^{12}$CO($J = 4 → 3$) are the lowest transitions that have been detected to date. Based on our results in the previous paragraph, however, we can now estimate their $L_{\text{CO}}^{12}$ by assuming constant brightness temperature for all transitions from $^{12}$CO($J = 1 → 0$) to $^{12}$CO($J = 4 → 3$) (i.e., $L_{\text{CO}}^{12}$ is the same for those transitions). This assumption is also in agreement with observations toward the radio galaxy 4C 60.07 (Greve et al. 2004). However, it is important to note that all high-$z$ sources were selected via higher $J$ CO transitions, which could, in principle, introduce a bias toward highly excited starburst environments.

Following Sanders et al. (1991), Gao & Solomon (2004) found a nonlinear relation between the logarithms of the FIR luminosity $L_{\text{FIR}}$ and the $^{12}$CO($J = 1 → 0$) line luminosity $L_{\text{CO}}^{12}$ for a sample of local spiral galaxies, luminous infrared galaxies, and ultraluminous infrared galaxies. Their sample consists mostly of galaxies whose FIR luminosity is powered by star formation only. Our $^{12}$CO($J = 1 → 0$) observations and LGV models suggest that $L_{\text{CO}}^{12}$ can be estimated for all CO-detected high-$z$ sources with some degree of confidence, even if only observations of higher $J$ CO transitions exist for most of these sources. To put this result into context, we now aim to discuss the $L_{\text{CO}}^{12}−L_{\text{FIR}}$ relation and its implications for some selected samples of galaxies at low and high redshift.

Figure 5 shows the relationship between $\log L_{\text{FIR}}$ and $L_{\text{CO}}^{12}$ for our three targets, all other high-$z$ CO detections (except TN J0924−2201, which does not have a measured FIR luminosity), the $z < 0.2$ Palomar-Green (PG) QSOs from Alloin et al. (1992), Evans et al. (2001), and Scoville et al. (2003) including PDS 456 (Yun et al. 2004), local ($z < 0.3$) ULIRGs from Solomon et al. (1997), and the local galaxy sample ($z < 0.1$) of Gao & Solomon (2004). All FIR luminosities for the high-$z$ sources are redetermined as described by Carilli et al. (2005) unless stated otherwise. Lensing magnification factors were taken into account. In addition, data for the Milky Way disk (Fixsen et al. 1999) and an (extrapolated) relation for Galactic molecular clouds (Mooney & Solomon 1988) are given for comparison. The solid line is a straight-line least-squares fit to the Gao & Solomon (2004) sample, corresponding
to log $L_{\text{FIR}} = (1.26 \pm 0.08) \log L_{\text{CO}} - 0.81$ (the power-law index is $1.25 \pm 0.08$ in the original publication). Fitting the high-$z$ sources, the Gao & Solomon (2004) data, the Solomon et al. (1997) ULIRGs, and the PG QSOs together, we find the relation log $L_{\text{FIR}} = (1.39 \pm 0.05) \log L_{\text{CO}} - 1.76$. Both relations are clearly nonlinear, as their power-law indexes are significantly larger than unity (see also the corresponding discussion in Gao & Solomon 2004). We recover a Schmidt-Kennicutt law (power-law index of 1.4; Kennicutt 1998a, 1998b) for the larger, more heterogeneous sample. More importantly, the high-$z$ sources seem to follow the same slope (within the errors) as seen at low $z$, even though most high-$z$ sources harbor central active galactic nuclei (AGNs). In addition, the high-$z$ QSOs show significantly larger luminosities than the lower-$z$ spirals, starbursts, and ULIRGs. This picture is supported by the finding that ULIRGs harbor large quantities of dense molecular gas, which is more intimately involved with star formation than the major fraction of the mostly diffuse CO (Gao & Solomon 2004). It has to be kept in mind that the high-$z$ sources are highly selected and probably fulfill the Malmquist bias (i.e., the apparent increase in the average $L_{\text{CO}}$ and $L_{\text{FIR}}$ toward high redshift is

![Graph showing comparison of CO line luminosity with FIR luminosity for a sample of low-$z$ spiral and starburst galaxies from Gao & Solomon (2004), the ULIRGs from Solomon et al. (1997), $z < 0.2$ PG QSOs from Alloin et al. (1992), Evans et al. (2001), and Scoville et al. (2003), extrapolated Galactic molecular clouds (GMCs) from Mooney & Solomon (1988), the Milky Way (Fixsen et al. 1999), and high-$z$ submillimeter galaxies, radio galaxies, and QSOs from the literature (see Solomon & Vanden Bout 2005) with respect to our new results. All FIR luminosities are rederived as described in Carilli et al. (2005). All data are corrected for gravitational lensing. The solid line is a straight-line least-squares fit to the Gao & Solomon (2004) sample, corresponding to log $L_{\text{FIR}} = (1.26 \pm 0.08) \log L_{\text{CO}} - 0.81$. The dotted line shows the fit to the GMCs from Mooney & Solomon (1988), corresponding to a power-law index of $0.96 \pm 0.08$. The dashed line is a fit to all high-$z$ sources, the Gao & Solomon (2004) data, the Solomon et al. (1997) ULIRGs, and the PG QSOs, corresponding to log $L_{\text{FIR}} = (1.39 \pm 0.05) \log L_{\text{CO}} - 1.76$.]

FIG. 5.—Comparison of velocity-integrated CO line luminosity with FIR luminosity for a sample of low-$z$ spiral and starburst galaxies from Gao & Solomon (2004), the ULIRGs from Solomon et al. (1997), $z < 0.2$ PG QSOs from Alloin et al. (1992), Evans et al. (2001), and Scoville et al. (2003), extrapolated Galactic molecular clouds (GMCs) from Mooney & Solomon (1988), the Milky Way (Fixsen et al. 1999), and high-$z$ submillimeter galaxies, radio galaxies, and QSOs from the literature (see Solomon & Vanden Bout 2005) with respect to our new results. All FIR luminosities are rederived as described in Carilli et al. (2005). All data are corrected for gravitational lensing. The solid line is a straight-line least-squares fit to the Gao & Solomon (2004) sample, corresponding to log $L_{\text{FIR}} = (1.26 \pm 0.08) \log L_{\text{CO}} - 0.81$. The dotted line shows the fit to the GMCs from Mooney & Solomon (1988), corresponding to a power-law index of $0.96 \pm 0.08$. The dashed line is a fit to all high-$z$ sources, the Gao & Solomon (2004) data, the Solomon et al. (1997) ULIRGs, and the PG QSOs, corresponding to log $L_{\text{FIR}} = (1.39 \pm 0.05) \log L_{\text{CO}} - 1.76$. (the Cloverleaf) reveals that only $\sim 20\%$ of its FIR luminosity is powered by star formation (Solomon et al. 2003), but it is not an outlier in the $L_{\text{CO}}-L_{\text{FIR}}$ diagram. In this context, the elevated $L_{\text{FIR}}/L_{\text{CO}}$ ratio in APM 08279+5255 may be explained by a combination of differential lensing and a relatively high contribution of the AGN to $L_{\text{FIR}}$ (see Rowan-Robinson 2000 for models of the IR SED). Outliers such as APM 08279+5255 are also found at low $z$ (e.g., the QSO PDS 456 and the warm ULIRG IRAS 08572+3915; see Fig. 5). As the relative number of such outliers is very small, this may also be explained by a brief FIR-bright AGN phase (Yun et al. 2004). However, it is likely that the dominant energy source in most ULIRGs is an extreme starburst rather than heating by a dust-enshrouded AGN (e.g., Solomon et al. 1997; Downes & Solomon 1998). This picture is supported by the finding that ULIRGs harbor large quantities of dense molecular gas, which is more intimately involved with star formation than the major fraction of the mostly diffuse CO (Gao & Solomon 2004). It has to be kept in mind that the high-$z$ sources are highly selected and probably fulfill the Malmquist bias (i.e., the apparent increase in the average $L_{\text{CO}}$ and $L_{\text{FIR}}$ toward high redshift is
probably a consequence of the flux limitation in the sample; e.g., Sandage 1994). As an additional consequence of flux limitation in the sample, lensing influences the results (i.e., stronger lensing magnification allows us to probe deeper, and therefore the intrinsic CO luminosity drops).

We can also set an approximate lower limit on the duration of the intense starburst phase. Considering the total H$_2$ masses and star formation rates in Table 2, the depletion timescale of the molecular gas is of the order of 10$^7$ yr for all three QSOs under the assumption of a constant SFR and 100% star-forming efficiency. This implies that the starburst itself can be relatively short-lived (and compact, as the dynamical time must be less than the starburst lifetime), unless the molecular gas in which the star formation occurs can be resupplied on timescales of $\sim$10$^7$ yr.

5. SUMMARY

We have detected $^{12}$CO($J = 1 \rightarrow 0$) emission in three QSOs at redshifts $3 < z < 4.7$ with the NRAOGBT and the MPIfR Effelsberg telescope. From our analysis of the resulting spectra of BR 1202$-0725$, PSS 2322$+1944$, and APM 08279$+5255$, we obtain the following results:

1. We derived lensing-corrected $^{12}$CO($J = 1 \rightarrow 0$) line luminosities of 1.0 $\times$ 10$^{11}$ K km s$^{-1}$ pc$^2$ for BR 1202$-0725$, 4.2 $\times$ 10$^{10}$ K km s$^{-1}$ pc$^2$ for PSS 2322$+1944$, and 1.4 $\times$ 10$^{10}$ K km s$^{-1}$ pc$^2$ for APM 08279$+5255$. These results are in good agreement (within a factor of 2) with previous estimates of the total CO luminosities based on the higher $J$ CO transitions, consistently providing very large $M_{\text{gas}}$(H$_2$) of $\sim$10$^{10}$ $M_\odot$.

2. $^{12}$CO($J = 1 \rightarrow 0$) fluxes predicted by one-component LVG models are in good agreement with our observations. Considering our modeling results, the CO emission appears to be close to thermalized up to the $4 \rightarrow 3$ transition in all cases. Thus, our observations show no indication of a luminous extended, low surface brightness gas component in any of the high-redshift QSOs in our sample (cf. Papadopoulos et al. 2001).

In fact, all CO transitions are described very well by a single gas component in which all molecular gas is concentrated in a compact circumnuclear region. If such extended components were to exist, our observations and models would limit their contribution to the overall luminosity to at most 20%–30%.

3. There appears to be a correlation between log $L_{\text{FIR}}$ and log $L_{^{12}\text{CO}}$ for low-redshift galaxies including (U)LIRGs over orders of magnitude in $L_{\text{FIR}}$, and the significantly brighter sources found at high z appear to follow the same general trend (see also Solomon & Vanden Bout 2005). In particular, we find that the correlation shows no significant difference between QSOs and systems without a luminous AGN.

The observations presented herein demonstrate the feasibility of detecting high-z CO with 100 m single-dish radio telescopes and highlight the physical implications of observing the ground-state transition of this molecule toward massive galaxies at redshifts greater than 4.

The National Radio Astronomy Observatory is operated by Associated Universities, Inc., under cooperative agreement with the National Science Foundation. We would like to thank the staff at the GBAT, in particular J. Braatz, G. I. Langston, and R. J. Maddalena, for their extensive support and many helpful discussions. D. R. acknowledges support from Deutsche Forschungsgemeinschaft (DFG) Priority Programme 1177. C. C. acknowledges support from the Max-Planck-Gesellschaft and the Alexander von Humboldt-Stiftung through the Max-Planck-Forschungspreis. We thank the referee for many useful comments that helped to improve the manuscript.
