Abstract

Background: High coverage of personal protection measures that kill mosquitoes dramatically reduce malaria transmission where vector populations depend upon human blood. However, most primary malaria vectors outside of sub-Saharan Africa can be classified as "very zoophagic," meaning they feed occasionally (<10% of blood meals) upon humans, so personal protection interventions have negligible impact upon their survival.

Methods and Findings: We extended a published malaria transmission model to examine the relationship between transmission, control, and the baseline proportion of bloodmeals obtained from humans (human blood index). The lower limit of the human blood index enables derivation of simplified models for zoophagic vectors that (1) Rely on only three field-measurable parameters. (2) Predict immediate and delayed (with and without assuming reduced human infectivity, respectively) impacts of personal protection measures upon transmission. (3) Illustrate how appreciable indirect communal-level protection for non-users can be accrued through direct personal protection of users. (4) Suggest the coverage and efficacy thresholds required to attain epidemiological impact. The findings suggest that immediate, indirect, community-wide protection of users and non-users alike may linearly relate to the efficacy of a user's direct personal protection, regardless of whether that is achieved by killing or repelling mosquitoes. High protective coverage and efficacy (>80%) are important to achieve epidemiologically meaningful impact. Non-users are indirectly protected because the two most common species of human malaria are strict anthropophages. Therefore, the small proportion of mosquitoes that are killed or diverted while attacking humans can represent a large proportion of those actually transmitting malaria.

Conclusions: Simplified models of malaria transmission by very zoophagic vectors may be used by control practitioners to predict intervention impact interventions using three field-measurable parameters; the proportion of human exposure to mosquitoes occurring when an intervention can be practically used, its protective efficacy when used, and the proportion of people using it.

Introduction

Indoor residual spraying (IRS) and long-lasting insecticidal nets (LLIN) dramatically reduce malaria transmission [1]. Both approaches exceed the benefits of community-wide protection for users and non-users alike once reasonably high coverage is achieved (30%–60%) [2–3]. High demographic coverage of humans (C_h) can dramatically reduce the density, longevity and infection prevalence of mosquito species that primarily feed indoors (endophagic) upon humans (anthropophagic) such as Anopheles gambiae and An. funestus from sub-Saharan Africa [4–6] or An. punctulatus and An. kolensis from the Pacific [7]. The massive importance of community-level transmission suppression for realizing the full potential of both IRS [8] and LLINs [2] using contact insecticides is well established and reflected in global universal coverage targets for these interventions [9]. Also, vector population modification by LLINs and/or indoor residual spraying (IRS) [4–5,10–12], has been observed since the Global Malaria Eradication Programme (GMEP) was initiated in the 1950s. For example, An. funestus was replaced by An. rivulorum and/or An. parensis following the introduction of IRS on at least three distinct occasions in South Africa, Kenya and Tanzania [13–16].
However, mosquitoes which feed upon animals (zoophagic) are primary malaria vectors in many tropical countries [17–18] and can dominate residual transmission in settings where high demographic coverage of LLIN or IRS has successfully suppressed previously predominant, anthropophagic species [4–5,10,12–13].

While LLINs confer personal protection against any mosquitoes attempting to bite while they are in use, it remains unclear whether they confer community-level protection against zoophagic vectors that feed on humans or on other and calculated in terms of basic individual availability and the expression of malaria transmission and control intensity. The mean availability of blood from individual protected, unprotected human and cattle respectively. The subscripts and the basic parameters presented here are also defined in table 1 with their dimensions listed for a quick reference.

Model Equations for Derived Parameters

We present equations from previous model [6] that are of important to this paper relating all derived parameters in terms of the basic parameters or other already derived parameters. Though these derived parameters are defined here, their definitions and dimensions are also presented in table 2.

Protective Coverage and Baseline Human Blood Index

As previously [6], we define de facto protective coverage of humans \((C_{hp})\) as being the product of crude coverage \((C_h)\) and the maximum proportion of human exposure to mosquitoes that can be directly prevented through personal protection by using a given intervention \((\pi)\):

\[ C_{hp} = \pi C_h. \]  

(1)

The mean availability \((\bar{a})\) of any host of any species \((s)\) for mosquitoes to attack is the product of the rate at which individual vectors encounter this host \((s)\) and the feeding probability upon that particular host \((\phi_s)\); \(z_i = \bar{a} \phi_s \). Thus, \(z_h = \bar{a}_h \phi_h \) and \(z_c = \bar{a}_c \phi_c \) represent mean availability of blood from individual protected, unprotected human and cattle respectively. The total availability of host \((A)\), protected humans \((A_{hp} = \bar{a}_h \phi_h N_h C_{hp})\), unprotected humans \((A_{hu} = \bar{a}_u \phi_u N_u (1 - C_{hp}))\), and all cattle \((A_c = \bar{a}_c \phi_c N_c)\), respectively, are the rates at which a single mosquito encounters, attacks single person of either protection status [6]. Mortality probability upon attacking a protected or an unprotected human or cow are denoted by \(\mu_p, \mu_u\), and \(\mu_c\), respectively. \(P_s\) denotes the survival probabilities during host-seeking and oviposition site-seeking, which are assumed to be equal. \(N_h\) and \(N_c\) are the population sizes of unprotected humans and cattle, respectively. The important and measurement of \(\pi\), but the concept was also discussed during the GMEP era [24–25] when the difficulty of controlling exophagic or exophilic vectors was described in Africa [21,26], Asia [27], and the Americas [23]. We also introduce host-encounter rate \((\pi)\) which is the rate at which a single host-seeking mosquito encounters a given single host. The notations, \(S_h, \gamma_h, \gamma_u\), and \(\gamma_c\) represent probability of attacking encountered protected humans, unprotected humans and cattle, respectively. Where, \(S_h\), and \(\gamma_c\) represent mosquito feeding probability upon protected humans, unprotected and cattle respectively. The mean attack availability of individual cattle \((\bar{a}_c)\) is the rate at which a single mosquito encounters and then attacks a single cow whereas the mean attack availability of an individual unprotected \((\bar{a}_u)\) human, is the rate at which a single mosquito encounters and then attacks a such single person of either protection status [6].

Model Description

We extended a static malaria transmission model [6] to explore the dependence of malaria transmission and control upon human malaria exposure for the zoophagic vectors that are primary vectors in many parts of the world [4,10,18] and will increasingly dominate transmission in the future [12,20]. We also contrast these impacts and underlying mode of action with those of the anthropophagic species that have been the overwhelming focus of malaria research and control to date.

Methods

Simulating Malaria Transmission and Control as a Function of Mosquito Host Preference

Before describing how the model simulations were performed, we first present the basic input parameters and their definitions, equations and derived parameters, output from the model, description of simplified models for very zoophagic vectors, and the expression of malaria transmission and control as a function of baseline human blood index.

Model Basic Input Parameters and Definitions

Several subspecies are used in this model; \(\Omega\) denotes an intervention package scenario consisting of a specific coverage, \(\Omega\) for a baseline condition with no intervention, \(\pi\) for protected or \(u\) for unprotected humans \((h)\), ande for cattle or other animals. Demographic or crude coverage is defined as a proportion of people using a personal protection measure as estimated in a standardized malaria indicator surveys \((C_h)\) [6]. Another important input is the proportion of daily exposure that a non-user would typically experience at times when a user would normally use such a personal protection measure \((\pi)\). In other words, this is the maximum proportion of human exposure to mosquitoes that can be directly prevented through a personal protection by using a given intervention. This is a broader definition than used previously when the term was described as the proportion of human exposure that occurs indoors while asleep at times when LLINs can be used \((\pi)\) [21]. This more generalized definition allows the incorporation of other personal protection interventions such as insecticide-treated clothing and repellents which can also be used outdoors. Recently, several authors [21–23] have described and discussed the importance and measurement of \(\pi\), but the concept was also discussed during the GMEP era [24–25] when the difficulty of controlling exophagic or exophilic vectors was described in Africa [21,26], Asia [27], and the Americas [23]. We also introduce host-encounter rate \((\pi)\) which is the rate at which a single host-seeking mosquito encounters a given single host. The notations, \(S_h, \gamma_h, \gamma_u\), and \(\gamma_c\) represent probability of attacking encountered protected humans, unprotected humans and cattle, respectively. Where, \(S_h\), and \(\gamma_c\) represent mosquito feeding probability upon protected humans, unprotected and cattle respectively. The mean attack availability of individual cattle \((\bar{a}_c)\) is the rate at which a single mosquito encounters and then attacks a single cow whereas the mean attack availability of an individual unprotected \((\bar{a}_u)\) human, is the rate at which a single mosquito encounters and then attacks a such single person of either protection status [6]. Mortality probability upon attacking a protected or an unprotected human or cow are denoted by \(\mu_p, \mu_u\), and \(\mu_c\), respectively. \(P_s\) denotes the survival probabilities during host-seeking and oviposition site-seeking, which are assumed to be equal. \(N_h\) and \(N_c\) are the population sizes of unprotected humans and cattle, respectively. The subscripts and the basic parameters presented here are also defined in table 1 with their dimensions listed for a quick reference.

Model Equations for Derived Parameters

We present equations from previous model [6] that are of important to this paper relating all derived parameters in terms of the basic parameters or other already derived parameters. Though these derived parameters are defined here, their definitions and dimensions are also presented in table 2.

Protective Coverage and Baseline Human Blood Index

As previously [6], we define de facto protective coverage of humans \((C_{hp})\) as being the product of crude coverage \((C_h)\) and the maximum proportion of human exposure to mosquitoes that can be directly prevented through personal protection by using a given intervention \((\pi)\):

\[ C_{hp} = \pi C_h. \]  

(1)

The mean availability \((\bar{a})\) of any host of any species \((s)\) for mosquitoes to attack is the product of the rate at which individual vectors encounter this host \((s)\) and the feeding probability upon that particular host \((\phi_s)\); \(z_i = \bar{a} \phi_s \) thus, \(z_h = \bar{a}_h \phi_h \) and \(z_c = \bar{a}_c \phi_c \) represent mean availability of blood from individual protected, unprotected human and cattle respectively. The total availability of host \((A)\), protected humans \((A_{hp} = \bar{a}_h \phi_h N_h C_{hp})\), unprotected humans \((A_{hu} = \bar{a}_u \phi_u N_u (1 - C_{hp}))\), and all cattle \((A_c = \bar{a}_c \phi_c N_c)\), respectively, are the rates at which a single mosquito encounters, attacks single person of either protection status [6].

\[ A = A_{hp} + A_{hu} + A_c. \]  

(2)
Table 1. Definition of basic parameters.

| Symbol | Definition and explanation | Dimension |
|--------|----------------------------|-----------|
| \( e \) | Host-eounter rate: rate at which a single host-seeking mosquito encounters a given single host. | One |
| \( e_h, e_c \) | Human and cattle encounter rate respectively. | Per Time |
| \( q_{h,u} \) | Probability that a mosquito which attacks an unprotected human will successfully feed upon that host. | One |
| \( q_{h,p} \) | Probability that a mosquito which attacks protected human will successfully feed upon that host. | One |
| \( \phi_{h,u}, \phi_{h,p}, \phi_{c} \) | represent probability of encountering protected, unprotected human and cattle respectively. | |
| \( N_h, N_{h,h}, N_{h,u} \) | Number of people, protected and unprotected | |
| \( N_c \) | Number of cattle | |
| \( C_n \) | Demographic or crude coverage: Proportion of people using a personal protection measure as estimated in a standardized malaria indicator surveys. | One |
| \( h_{hu} \) | Mortality probability upon attacking an unprotected human. | One |
| \( h_{hp} \) | Mortality probability upon attacking an protected human | One |
| \( e_c \) | Mortality probability upon attacking a cattle | One |
| \( e_1 \) | The proportion of normal exposure to mosquito bites upon humans lacking LLINs, which occurs indoors at times when nets would normally be in use. | One |
| \( e_2 \) | The maximum proportion of human exposure to mosquitoes that can be directly prevented through personal protection by using a given intervention | One |
| \( P_{ov} \) | The survival probabilities during host seeking and oviposition site-seeking assumed to be equal | 1/exp(Time) |

The subscripts used are given in bracket; human (h), protected (p), unprotected (u), cattle (c), a baseline condition with no personal protection coverage (0), intervention package scenarios consisting of a specific coverage (Ω)

\[
Q_{h,0} = \frac{e_h \phi_{h,u} N_h}{e_h \phi_{h,0} N_h + e_c \phi_{c} N_c}. \quad (5)
\]

For predominantly animal-feeding mosquito [29], we assume that the mean encounter rate for humans \((e_h)\) approaches zero, so that the same is correspondingly true of the mean attack availability of humans \((a_h)\) and the mean availability of human blood per se \((zh)\). Therefore, the total attack availability of all humans \((A_h)\) and the total availability of all human blood per se \((Z_h)\) also approaches zero.

In equation 5, baseline human blood index goes to zero \((Q_{h,0} \rightarrow 0)\) when either the denominator goes to infinity or the numerator goes to zero. The numerator can go to zero in three different ways; either when \(e_h \rightarrow 0\) or \(N_h \rightarrow 0\) or \(\phi_{h,u} \rightarrow 0\). It is unrealistic that the denominator will go to infinity, or that \(\phi_{h,u}\)will go to 0, and it is of no interest to model malaria transmission in the situation where \(N_h\) goes to zero. So, in the situations that are realistic and interesting, \((Q_{h,0} \rightarrow 0)\)if and only if \(e_h \rightarrow 0\). Hence, when we are interested in the situation \((Q_{h,0} \rightarrow 0)\), we can take the limit as \(e_h \rightarrow 0\),which biologically means a situation where mosquitoes are not attracted to human blood so the attractiveness or availability of human blood is close to zero. Therefore, the mean availability of individual humans \((a_h)\) and the mean availability of blood from individual humans \((zh)\), the total availability of all humans \((A_h)\), and the total availability of all humans blood \((Z_h)\), including both the protected and unprotected, all approach zero as well.

Model Outputs

Malaria transmission intensity is often expressed in terms of the entomologic inoculation rate (EIR) which is a direct, field-
Table 2. Definitions of the derived parameters.

| Symbol   | Definition and explanation                                                                 | Units            |
|----------|-------------------------------------------------------------------------------------------|------------------|
| C<sub>hp</sub> | Protective coverage                                                                        | One              |
| a<sub>c</sub> | Mean availability of individual cow for attack: rate at which a single mosquito encounters and then attacks a cow or pseudo-host. | Per time per animal |
| a<sub>h</sub> | Mean availability of individual human for attack: rate at which a single mosquito encounters and then attacks a human or pseudo-host. | Per time per human |
| a<sub>hp</sub> | Availability of individual protected human                                                  | Per time per protected human |
| a<sub>hu</sub> | Availability of individual unprotected human                                                | Per time per unprotected human |
| A, A<sub>h</sub>, A<sub>c</sub> | Total availability of all hosts, all humans and all cattle, respectively: rate at which a single mosquito encounters, attacks upon these host sets | Per time |
| Z, Z<sub>h</sub>, Z<sub>c</sub> | Mean availability of blood from all hosts, all humans and all cattle, respectively: rate at which a single mosquito encounters, attacks and successfully feeds upon these host sets. | Per time |
| Z, Z<sub>h</sub>, Z<sub>c</sub> | Total availability of blood from all hosts, all humans and all cattle, respectively: rate at which a single mosquito encounters, attacks and successfully feeds upon these host sets. | Per time |
| Q<sub>h</sub> | Human blood index: the proportion of all blood meals from all hosts which are obtained from humans. | One |
| Q<sub>h,0</sub> | The baseline human blood index in the absence of any protection measure                    | One |
| P<sub>f</sub> | Probability of surviving host attack per feeding cycle                                      | Time |
| f<sub>o</sub> | Oviposition site-seeking interval: number of days a mosquito takes to find an oviposition site once it starts searching for it | Time |
| f<sub>v</sub> | Host seeking interval: number of days a mosquito takes to find and attack a vertebrate host | Time |
| f<sub>w</sub> | The survival rate per feeding cycle                                                        | Per time |
| f | Feeding cycle length: measured as the number of days it takes a single mosquito to get from one blood feed to the next. | Time |
| E | Emergence rate of mosquito vector                                                          | Per time |
| b<sub>h</sub> | The total number of infectious bites on all humans                                         | One |
| b | The total number of sporozoite infected bites in all hosts per mosquito lifetime            | One |
| EIR<sub>h,0</sub> | Entomological inoculation rate (mean number of infectious bites that an average individual human receives per year). | Per time |
| EIR<sub>h,p</sub> | absolute EIR for an average community member in a given intervention scenario              | Per time |
| EIR<sub>h,u</sub> | EIR for non-users                                                                          | Per time |
| η<sub>hu</sub> | The immediately relative exposure of non-users benefiting only from communal protection    | One |
| g<sub>h</sub> | Gestation interval: number of days a mosquito takes to digest a blood meal and return to searching for oviposition site. | Time |
| ρ<sub>h</sub> | Combined probability that a vector survives gestation                                       | One |
| x | Mosquito age                                                                              | Time |
| S<sub>x</sub> | The sporozoite infection prevalence of mosquitoes at each age                               | One |
| h | Human infectiousness to mosquitoes: probability of a vector becoming infected per human bite. | One |
| P<sub>h</sub> | Overall proportion of personal protection against mosquito bites provide by using a given protective measure. | One |
| P<sub>u</sub> | The immediate impact on vector population assuming a reduction of human infectivity.        | One |
| P<sub>hu</sub> | Estimation of daily cycle and cumulative survival of mosquitoes up to each age (x).        | One |

The subscripts used are given in bracket; human (h), protected (p), unprotected (u), animals (c), a baseline condition with no personal protection coverage (0), intervention package scenarios consisting of a specific coverage (Ω).

doi:10.1371/journal.pone.0037661.t002

measurable indicator of human exposure to bites of mosquitoes infected with transmissible sporozoite stage malaria parasites [30–31]. Thus, the primary outputs from the model were the absolute EIR for an average community member (EIR<sub>h,0</sub>) and the relative exposure for non-users to the baseline condition (η<sub>h,u</sub>·Ω) both in a given intervention scenario. To help understand how the impact of a personal protection measure mediated in a given scenario (Ω), the impact upon vector population parameters, the survival rate per feeding cycle (P<sub>f</sub>·Ω), human blood index (Q<sub>h,Ω</sub>), feeding cycle length(f<sub>Ω</sub>), and emergence rate of adult mosquitoes (E<sub>Ω</sub>) are plotted against (Q<sub>h,0</sub>), as intermediate secondary outputs that underlie EIR and changes in this primary outcomes.

We present equations from Killean et al [6] necessary to define primary and secondary outputs in terms of basic or already derived parameters. The probability of surviving host attack per feeding cycle (P<sub>f</sub>) is a function of the probability of surviving one complete feeding cycle (P<sub>f</sub>·Ω). The oviposition site-seeking interval (η<sub>o</sub>) and the vertebrate host-seeking interval (η<sub>v</sub>) are both a function of feeding cycle length (f) andP<sub>f</sub>, where both P<sub>f</sub>·Ω and f are functions of emergence rate of adult mosquitoes (E) [6]. So,
we first present equations of $P_i$, and the combined $\eta_o$ and $\eta_v$:

$$P_i = 1 - \left( \frac{\mu_{b,o} A_{b,o} + \mu_{b,v} A_{b,v} + \mu_b A_c}{A_{b,p} + A_{b,v} + A_c} \right).$$  \label{eqn:pi}

\begin{align}
\eta_o + \eta_v &= \frac{1}{A} + \frac{1}{Z} = \frac{1}{A_b + A_c} + \frac{1}{Z_b + Z_c}.
\end{align}  \label{eqn:eta}

Hence, $P_f, f, E$ [6] are given as follows:

$$P_f = P^f f_P^o + \eta_o P_i.$$  \label{eqn:p_f}

$$g + \frac{1}{A} + \frac{1}{Z} = g + \frac{1}{A_b + A_c} + \frac{1}{Z_b + Z_c}.$$  \label{eqn:g}

$$E = \sum_{x=1}^{\infty} \frac{P_x^{f,f}}{f}.$$  \label{eqn:e}

Where $g$ is gestation period and $P$ is the mean daily survival, $P^f$ is the probability that a vector survives a single gestation, and $P_p^o$ is the survival probability for the combined host seeking and oviposition site-seeking intervals. Whereas, $P_f^{f,f}$ is the cumulative survival of mosquitoes up to a given age ($x$), as previously described [6]. In all cases, impact is assessed in terms of changes in the parameters under a given scenario ($\Omega$) relative to a baseline with no protection measure ($0$); $P_{f,i}^\Omega$, $\eta_{0}^\Omega$, $\beta$ and $\delta$, respectively.

The number of infectious bites on humans ($\beta_h$) per mosquito lifetime is given by the product of human blood index and the sum of the products of the probabilities of surviving and being infectious at each age [6]:

$$\beta_h = \frac{Q_h}{f} \sum_{x=1}^{\infty} S_x P_x^{f,f}.$$  \label{eqn:beta_h}

Whereas, $S_x$ is the sporozoite infection prevalence of mosquitoes at each age $x$, $S_x = S_x - 1 + (x Q_h (1 - S_x - 1))/f$, for $x > n$ otherwise $S_x = 0$ where, $n$ is the extrinsic incubation period, and $\kappa$ is population mean human infectiousness to mosquitoes; defined as the mean probability of a vector becoming infected per human bite.

Thus, absolute EIR for an average community member in a given intervention scenario ($EIR_{b,\Omega}$) is given by [6]:

$$EIR_{b,\Omega} = \frac{\beta_h E}{N_b}.$$  \label{eqn:eir}

The relative exposure for non-users ($\psi_{b,\Omega}$), humans who are unprotected ($\Omega$) by the physical and chemical barrier of personal protection measure but may benefit from communal protection, in a given intervention ($\Omega$) scenario is calculated as their predicted exposure ($EIR_{b,\Omega}$) divided by their baseline exposure with no protection ($0$) measure ($EIR_{b,0,\Omega}$), as:

$$\psi_{b,\Omega} = \frac{EIR_{b,\Omega}}{EIR_{b,0,\Omega}}.$$  \label{eqn:psi}

$$\psi_{b,\Omega} = \frac{z_{h,h} Q_h E}{z_{b,h} Q_b E} = \frac{z_{h,h} Q_h E}{z_{b,h} Q_b E}$$  \label{eqn:psi2}

Whereas, $\beta$ is the number of sporozoite infected bites in all hosts per mosquito lifetime ($\beta = \sum_{x=1}^{\infty} S_x P_x^{f,f}/f$) calculated as equation 11 but ignoring $Q_h$ term [6].

**Simplified Models for Very Zoophagic Vectors**

Initial simulations suggested closer examination of the underlying mechanisms through which personal protection mediates community-level protection against malaria transmission by very zoophagic mosquitoes. We specifically define very zoophagic vectors as those which are not merely zoophagic, such as An. arabiensis which readily feeds on both humans and cattle [32], but rather those which have a strong preference for animals and normally obtain 90% or more of their blood meals from animals ($Q_h,0 \leq 0.1$). A useful example of such a vector species that can be considered very zoophagic is *Anopheles cuculatus* in the Mekong delta of Vietnam. This mosquito population has a >11-fold preference for cattle over humans [27], which allows us to simulate transmission by this species by adjusting the mean encounter rate for humans ($\eta_o$) in proportion to this relative attack rate of cattle compared with humans [6,28,33], but which are otherwise equivalent to those described above for An. arabiensis [6]. It illustrates how mosquitoes exhibiting very high levels of zoophagy at population level ($Q_h,0 = 0.08$) can mediate transmission intensities ($EIR = 3.1$ infectious bites per person per year) that are compatible with this mosquito’s status as a primary malaria vector in the region [34].

**Expressing Malaria Transmission and Control as a Simplified Function of Baseline Human Blood Index**

We express the primary and secondary outputs in terms of human blood index ($Q_h,0$), because it is one of the most important determinants of overall malaria transmission locally and globally [17,19,35–37]. For very zoophagic malaria populations with low human blood indices (0 < $Q_h,0 < 0.1$) that are nevertheless sufficient to stably transmit malaria (0 < $EIR < 1$ infectious bite per year per person); we are interested in a situation where $Q_h,0 \rightarrow 0$ to illustrate the impact of a personal protection measure on $P_{f,i}^\Omega$, $E_0$ and $Q_{b,0}^\Omega$.

Since $P_p^o$ is constant, using equation 6 and 8 we can compute $P_{f,i}^\Omega$ as $Q_h,0 \rightarrow 0$ by taking the limit as $\eta_o \rightarrow 0$, (so $A_{b,p} \rightarrow 0, A_{b,v} \rightarrow 0, Z_{b,p} \rightarrow 0, Z_{b,v} \rightarrow 0$) terms only with subscript $c$ (for cattle) remain cancelling to 1:

$$\lim_{Q_h,0 \rightarrow 0} \frac{P_{f,i}^\Omega}{P_{f,c}^\Omega} = \frac{ps \frac{1}{a + b + c}}{ps \frac{1}{a + b + c}} \left( 1 - \frac{a b x + a c y + b c z}{a b c x + a c y + b c z} \right)$$  \label{eqn:lim}

$$= \frac{ps \frac{1}{a + b + c}}{ps \frac{1}{a + b + c}} \left( 1 - \frac{a b x + a c y + b c z}{a b c x + a c y + b c z} \right)$$  \label{eqn:lim2}

$$= \frac{ps \frac{1}{a + b + c}}{ps \frac{1}{a + b + c}} \left( 1 - \frac{a b x + a c y + b c z}{a b c x + a c y + b c z} \right) = 1.$$
Using equation 9 the same approach can be applied for \( \frac{f_0}{f_0} \) to get;

\[
\lim_{Q_{h,0} \to 0} f_0 = \frac{g + \frac{1}{\zeta_e} + \frac{1}{\zeta_c}}{g + \frac{1}{\zeta_e} + \frac{1}{\zeta_c}} = 1.
\]

We use equation 10 to drive \( \frac{E_0}{E_0} \) in the limit \( \varepsilon_0 \to 0 \) by rearranging equation 10 and then substituting \( P_{f,0} \), \( P_{f,0} \), and \( f_0 \) from equations 14 and 15 as follows;

\[
\lim_{Q_{h,0} \to 0} \frac{E_0}{E_0} = \frac{\sum_{i=1}^{\infty} \int_0^{1/P_{f,0}} f_{i,0} \times f_0}{\sum_{i=1}^{\infty} \int_0^{1/P_{f,0}} f_{i,0} \times f_0} = \frac{\sum_{i=1}^{\infty} (P_{f,0}(1 - \mu_i))^{1/\zeta_e} \times (g + \frac{1}{\zeta_c})}{\sum_{i=1}^{\infty} (P_{f,0}(1 - \mu_i))^{1/\zeta_c} \times (g + \frac{1}{\zeta_e})} = 1.
\]

The interpretation of equation 14, 15 and 16 is given in the result section. However, the limit for the other vector population parameter does not go to 1, indicating that human blood index is affected by personal protection measures against very zoophagic vectors that are nevertheless fractionally but sufficiently anthropophilic to put a lot of people at risk of malaria transmission. This allows much simpler models for both immediate impacts upon malaria transmission, with and without an assumed reduction of human infectivity in the longer term, to be derived that rationalize the reduced, but nevertheless useful, impacts of insecticidal personal protective measures upon zoophagic vectors. The explanation and interpretation of what happens to the overall impact on \( Q_{h,0} \) as \( Q_{h,0} \) approaches zero for very zoophagic \( (Q_{h,0} \leq 0.1) \) vectors, is provided in the results section.

Simulated Scenarios

The full possible range of host preference for mosquitoes was simulated by modifying field estimates for cattle and human encounter rate, \( (\varepsilon_c) \) and \( (\varepsilon_a) \) respectively, by beginning with values typical of a mosquito such as \( A. \) \textit{Arabienensis}, which is both anthropophilic and zoophilic [33,35,38–39]. The value for \( \varepsilon_c \) was tuned down to zero to mimic highly anthropophilic African vectors like \( A. \) \textit{gambiae} [33], while \( \varepsilon_a \) was tuned down towards zero to mimic zoophilic mosquitoes like \( A. \) \textit{quadriannulatus} [38,40] and other Anophelines that only occasionally feed on humans [38,41–42]. While \( A. \) \textit{gambiae}, \( A. \) \textit{arabienensis} and \( A. \) \textit{quadriannulatus} come from a single African species complex \( (A. \) \textit{gambiae sensu latu}); they span the full range of host choice preferences exhibited by anophelines world-wide. Although \( A. \) \textit{gambiae} typically feeds almost exclusively upon humans, and has historically been the most important vector of malaria in the world [43], \( A. \) \textit{arabienensis} is as likely to attack cattle as humans and is a correspondingly less potent but nevertheless significant primary vector [43–45]. By comparison, \( A. \) \textit{quadriannu-
Figure 1. The impact of long lasting insecticide treated nets (LLINs) upon malaria vector population parameters. Malaria vector population parameters, transmission intensity, and the impact of personal protection interventions upon them under a range of values for the proportion of blood meals obtained from humans ($Q_{b,0}$). In all panels, the x-axis is the proportion of all blood meals the vector population would obtain from humans in the absence of nets ($Q_{b,0}$). Low values of $Q_{b,0}$ represent mosquitoes that primarily feed on animals while high values represent mosquitoes that prefer to feed on humans. The y-axis for panel A represents the absolute entomological inoculation rate ($EIR$) for an average community member in a given scenario ($EIR_{h,0}$). The y-axes for all other panels represent relative values for mosquito population parameters, compared with those expected in the absence of LLINs: B: Relative exposure for non-users ($\psi_{D,B} = \frac{EIR_{h,B}}{EIR_{h,0}}$), C: Relative proportion of blood-meals taken from human ($\frac{Q_{b,0}}{Q_{b,0}}$), D: Relative probability of surviving one complete feeding cycle ($\frac{P_{r,0}}{P_{r,0}}$), E: Relative feeding cycle length ($\frac{L_{f,h}}{L_{f,0}}$), and F: Relative emergence rate of adult mosquitoes ($\frac{E_{0,h}}{E_{0,0}}$). In all cases the intervention scenario ($\Omega$) crude demographic coverage specified high levels of coverage ($C_d = 0.8$) and use at times when transmission would otherwise occur ($\pi_i = 0.9$). doi:10.1371/journal.pone.0037661.g001
animals are not protected and remain available to feed on. Therefore, negligible impact is expected upon mosquito survival equation 14, Figure 1C or upon feeding cycle length equation 15, Figure 1E, or upon reproduction rates equation 16, Figure 1F. Human blood index is the only parameter affected for very zoophagic vectors (Figure 1D) so it is important to explore what happens to \[ \frac{Qh}{Q_{h,0}} \] as \[ Q_{h,0} \] approaches zero.

Personal protection measures can deliver appreciable communal protection against transmission by zoophagic vectors (Figure 1B) because they can lower the proportion of bloodmeals obtained from humans (Figure 1D). Thus, further reducing already-low proportions of blood meals taken from humans (\[ Q_{h,0} \]), can have a corresponding immediate impact on the exposure of non-users lacking any personal protection against malaria transmission by zoophagic mosquitoes (Figure 1D). This is because the tiny proportion of a zoophagic mosquitoes population that are killed may be a large proportion of those that actually transmit human parasites such as *Plasmodium falciparum* and *P. vivax*.

**Calculating Immediate Impact of Personal Protection Upon Transmission by Very Zoophagic Vectors using only Three Input Parameters**

Next, we illustrate how the dependence of transmission and control enables derivation of much simpler models for both immediate and delayed impacts (with and without assumed reduced human infectivity, respectively) upon malaria transmission, to be derived that rationalize the reduced, but nevertheless useful, impacts of a personal protection measure upon zoophagic vector systems that are illustrated by the intercepts on the left hand side of Figures 1B and D.

So, as \[ Q_{h,0} \] approaches zero, the immediately relative exposure of non-users benefiting only from communal protection (\[ \psi_{h,u,0} \]) (Figure 2B), compared to their pre-intervention exposure can be calculated as follows; If we substitute equation for \[ P_{x} = 1 \text{ and } Z_{x} = \] 1 and \[ E_{x} = E_{0} \] 1 and \[ Z_{x} = 0 \] 1, since \[ Z_{x} = 0 \] as \[ \epsilon_{x} \rightarrow 0 \], then \[ \psi_{h,u,0} \] is given by:

\[
\psi_{h,u,0} = \lim_{Q_{h,0} \rightarrow 0} \frac{EIR_{h,u,0}}{EIR_{h,0,0}} = \frac{Q_{h,0}}{Q_{h,0}}
\]

Now, if we substitute the definition of \[ Q_{h} \] from equation 4, rearrange and substitute \[ z_{h,u} = \epsilon_{h} \phi_{h,u} \] and \[ z_{h,p} = \epsilon_{h} \phi_{h,p} \] where \[ \epsilon_{h} \] is human encounter rate [6], relative exposure of non-users (\[ \psi_{h,u,0} \]) is intuitively calculated as the mean of the feeding probabilities for protected (\[ \phi_{h,p} \]) and unprotected humans (\[ \phi_{h,u} \]), weighted according to the protective (\[ C_{h,p} \]) rather than simple demographic (\[ C_{h} \]) coverage:

\[
\psi_{h,u,0} = \lim_{Q_{h,0} \rightarrow 0} \frac{EIR_{h,u,0}}{EIR_{h,0,0}} = \frac{Q_{h,0}}{Q_{h,0}}
\]

\[
\phi_{h,p} = \phi_{h,u} \left( 1 - C_{h,p} \right) + \phi_{h,u} C_{h,p}
\]

In simple terms, the level of indirect communal protection afforded all community members is equivalent to the coverage-weighted mean of feeding probabilities (equation 18). This is, in turn, equivalent to the community-wide mean level of personal protection obtained as a coverage-weighted mean of personal protection. Relative exposure can also be expressed in terms of personal protection (\[ \rho \]), where [6];

\[
\rho = 1 - \frac{\phi_{h,p}}{\phi_{h,u}}.
\]

So, by substituting equations 1 and 19 into rearranged equation 18, the impact upon transmission by very zoophagic vector can be expressed in terms of only three field-measurable parameters: the proportion of human exposure to mosquitoes occurring when an intervention can be practically used (\[ \gamma \]), its protective efficacy when used (\[ \rho \]), and the proportion of people using it (\[ C_{h} \]):

\[
\lim_{Q_{h,0} \rightarrow 0} \psi_{h,u,0} = 1 - \rho C_{h,p} = 1 - \rho \pi C_{h},
\]

Of course communal protection is complemented by personal protection so the overall mean level of protection immediately obtained across all users and non-users in the community is calculated as the square of equations 18 and 20. Consistent with previous models [6,8,36,50–51,54–56], the immediate relative exposure of the average community member (\[ \psi_{h,0} \]) is equivalent to the ratio of the square of the pre and post intervention human blood index (\[ Q_{h} \]) values:

\[
\lim_{Q_{h,0} \rightarrow 0} \psi_{h,0} = \left( \frac{Q_{h,0}}{Q_{h,0}} \right)^{2} = \left( \frac{\phi_{h,p} (1 - C_{h,p}) + \phi_{h,u} C_{h,p}}{\phi_{h,u}} \right)^{2} = \left( 1 - \rho \pi C_{h} \right)^{2}
\]
In direct, intuitive terms, this is because a mosquito has to bite humans twice to transmit malaria parasites.

Delayed Impacts Including Reduced Human Infectiousness

The relatively low transmission intensities that very zoophagic mosquitoes mediate, also allow the reduction of infectiousness of the human population to mosquitoes to be approximated in a simplified manner. In addition to the direct and immediate impacts upon the vector population, reduction impacts upon infectiousness of human population to mosquitoes (\(k\)) may also be achieved [31,52] but only if mosquito to human transmission can be reduced below saturating levels (\(EIR < 10\) infectious bites per person per year) [57]. In holoendemic scenarios, with highly anthropophagic vectors, getting below this threshold will require high levels of coverage \(C_h \geq 0.8\) over long periods because re-equilibration of transmission and prevalence levels will take years rather than days, weeks or months [52,58]. At the expected intermediate levels of residual transmission (1 < \(EIR < 10\) infectious bites per person per year) expected for anthropophagic vector populations exposed to high intervention coverage (Figure 1A), the eventual impact upon EIR, resulting from direct
immediate impact on the vector population parameters combined with feedback upon human infectiousness is complex to predict [57–59].

While human infectiousness is saturated at high transmission levels (EIR ≥ 10), at the much lower levels expected for most very zoophagic vectors EIR ≤ 1, human infectiousness to mosquitoes is thought to be directly and approximately linearly related to mosquito to human transmission intensity in the previous few years k ≈ EIR. While impacts upon the vector population have an immediate effect on EIR (Figure 2A), no immediate impact upon infectiousness is expected (kΩ = k0) and it may take a long time for a long-lived blood stage infection to be cleared from the human population and the feedback of EIR upon k and r is very slow to re-equilibrate [49–50]. Assuming a linear relationship exists between these two variables at low values approaching the origin of Figure 1A, and that further reductions will be achieved as a result of re-equilibration between k and EIR, Then reduction of impact on human infectiousness to mosquitoes is expected to be greater than the immediate impact on EIR.

\[ \frac{k_\Omega}{k_0} < \psi_{h,\Omega} = \left( \frac{Q_{h,\Omega}}{Q_{h,0}} \right)^2 = \left( \frac{\phi_{hv}(1-C_{h,p}) + \phi_{h,p}(C_{h,p})}{\phi_{h,u}} \right)^2 \]

The combination of effects mediated by the immediate impact on vector population, and delayed impact on malaria parasite prevalence and mean infectiousness in the human population, is therefore assumed to at least the same as the product of the two:

\[ \psi_{h,\Omega} = \psi_{h,a,\Omega} \frac{k_\Omega}{k_0} = \left( \frac{Q_{h,\Omega}}{Q_{h,0}} \right)^4 = \left( \frac{\phi_{hv}(1-C_{h,p}) + \phi_{h,p}(C_{h,p})}{\phi_{h,u}} \right)^4 \]

Discussions

Human blood index, defined as the proportion of a mosquito population that feeds upon humans, is clearly as important a determinant of malaria transmission and control (Figure 1) today [29] as it was half a century ago [19]. In simple terms, the more a vector depends upon human blood, the greater will be the impact of personal protection measures upon their population density, longevity and transmission potential, and the greater will be the advantage of pesticides which act exclusively through contact toxicity over those relying upon repellency (Figure 1). However, the more zoophagic a mosquito species is, the more personal protection can act simply by blocking host-vector contact (Figure 1) so that it becomes increasingly irrelevant whether protection is achieved through toxicity or repellency so that a wider variety of target product profiles may be considered [60].

The world’s malaria vectors span the full range of baseline human blood indices considered here [17,19] so this remains a critical parameter for national control programmes to evaluate and consider when planning vector control campaigns. The findings from the models presented apply specifically to very zoophagic vectors, mosquitoes with a strong preference for zoophagic vectors, such as An. koliensis, that have dominated the thinking behind global malaria control policy [55] as it was half a century ago [19]. In simple terms, the more a vector depends upon human blood, the greater will be the impact of personal protection measures upon their population density, longevity and transmission potential, and the greater will be the advantage of pesticides which act exclusively through contact toxicity over those relying upon repellency (Figure 1). However, the more zoophagic a mosquito species is, the more personal protection can act simply by blocking host-vector contact (Figure 1) so that it becomes increasingly irrelevant whether protection is achieved through toxicity or repellency so that a wider variety of target product profiles may be considered [60].

Thresholds Necessary to Attain Epidemiological Impact

In all the panels of figure 2, the x-axis is the proportion of human non-user exposure to mosquito bites that occurs at times when a user would actually use the protective intervention(π), which was plotted in values decreasing from 0.9 to 0.1 in the interval of 0.1. The y-axis represents the proportion of mosquito bites prevented while actually using protective intervention obtained by taking the product of C0 = 0.8 and the values from equation 19. The z-axes reflects immediate (A and B) and delayed (C and D) impact upon relative exposure experienced by non-users. While the latter assumes that delayed effects upon human-to-mosquito transmission occur if immediate reductions in the ability of mosquitoes to mediate transmission to humans are sustained over a long time [52]. Therefore, figure 2 is produced as follows; the x-axis in all panel are π values decreasing from 0.9 to 0.1, the y-axis are calculated protective π values from the given expression. In other hand, a different equation was used for each panel to obtain values for z-axis by using corresponding π and protective π values substituted into equation 20 (A), equation 21 (B), product of values from equations 20 and 21 (C), and equation 23 (D).

In figure 2, the reader can note that the values in z-axes only start dropping substantially at higher values of π and y axes. Thus, figure 2 illustrates how these simplified models indicate that personal protection measures will need to be practically applicable at most times of the day when exposure can occur (π ≥ 0.8), confer high levels of person protection to users (ρ ≥ 0.8), and be used by the majority of human population (Cf ≥ 0.8), if they are to appreciably suppress malaria transmission by zoophagic vectors.

Discussion

Human blood index, defined as the proportion of a mosquito population that feeds upon humans, is clearly as important a determinant of malaria transmission and control (Figure 1) today [29] as it was half a century ago [19]. In simple terms, the more a vector depends upon human blood, the greater will be the impact of personal protection measures upon their population density, longevity and transmission potential, and the greater will be the advantage of pesticides which act exclusively through contact toxicity over those relying upon repellency (Figure 1). However, the more zoophagic a mosquito species is, the more personal protection can act simply by blocking host-vector contact (Figure 1) so that it becomes increasingly irrelevant whether protection is achieved through toxicity or repellency so that a wider variety of target product profiles may be considered [60].

The world’s malaria vectors span the full range of baseline human blood indices considered here [17,19] so this remains a critical parameter for national control programmes to evaluate and consider when planning vector control campaigns. The findings from the models presented apply specifically to very zoophagic vectors, mosquitoes with a strong preference for zoophagic vectors, such as An. gambiae, An. funestus and An. koliensis, that have dominated the thinking behind global malaria control policy [55] as it was half a century ago [19]. In simple terms, the more a vector depends upon human blood, the greater will be the impact of personal protection measures upon their population density, longevity and transmission potential, and the greater will be the advantage of pesticides which act exclusively through contact toxicity over those relying upon repellency (Figure 1). However, the more zoophagic a mosquito species is, the more personal protection can act simply by blocking host-vector contact (Figure 1) so that it becomes increasingly irrelevant whether protection is achieved through toxicity or repellency so that a wider variety of target product profiles may be considered [60].

The world’s malaria vectors span the full range of baseline human blood indices considered here [17,19] so this remains a critical parameter for national control programmes to evaluate and consider when planning vector control campaigns. The findings from the models presented apply specifically to very zoophagic vectors, mosquitoes with a strong preference for zoophagic vectors, such as An. gambiae, An. funestus and An. koliensis, that have dominated the thinking behind global malaria control policy [55] as it was half a century ago [19]. In simple terms, the more a vector depends upon human blood, the greater will be the impact of personal protection measures upon their population density, longevity and transmission potential, and the greater will be the advantage of pesticides which act exclusively through contact toxicity over those relying upon repellency (Figure 1). very simple models. These models use only three parameters which may potentially be measured in the field by National Malaria Control Programmes (NMCPs) and their supporting national institutional partners in developing countries: the maximum proportion of human exposure to mosquitoes that can be directly prevented through personal protection by using a given intervention, its protective efficacy when used, and the demographic coverage of human users. The relationship between entomologic inoculation rate (EIR) which is a direct, field-measurable indicator of human exposure to bites of mosquitoes infected with transmissible sporozoite stage malaria parasites [30–31] and the efficacy of a personal protection measure was derived through a model that logically describe the process of mosquito feeding cycle and malaria transmission.

The suggestion that the impact of personal protection upon malaria transmission by very zoophagic vectors may be independent of the mode of action of the product has substantial implications for manufacturers and NMCPs alike. Unlike transmission mediated by anthropophagic vectors [6,60], the impact upon malaria where zoophagic vectors predominate is a simple function of personal protective efficacy regardless of whether that arises from deterrent or toxic modes of action. Vapor-phase repellents [68–71] do not require direct physical contact with target insects. They can protect one or more individuals without comprehensively treating wall, roof, net, clothing or skin surfaces, so high levels of personal protection may be easier to achieve in practice [60] than with the contact toxins that are clearly superior for vectors that feed indoors upon humans [6]. Such spatial repellents may therefore be particularly applicable, and even preferable to contact toxins, where malaria transmission is predominantly mediated by very zoophagic vectors, especially where transmission primarily occurs outdoors. While we present

initial modeling results here, further empirical field testing of this model is essential to build solid evidence to guide malaria control programs.

Conclusion

We extended a published malaria transmission model to examine the relationship between transmission, control, and the baseline human blood index for very zoophagic vectors. The results from model is very simple and can be used by vector control practitioners to forecast the likely immediate and delayed impacts of personal protection measures using three parameters that may potentially be measured in the field: the proportion of human exposure to mosquitoes occurring when a intervention can be practically used, its protective efficacy when used, and demographic coverage of human users. High levels (≥80%) of protective coverage and efficacy are important to achieve an epidemiologically meaningful impact.
