Adiabatic field-free alignment of asymmetric top molecules with an optical centrifuge

A. Korobenko and V. Milner

(Dated: October 8, 2015)

We use an optical centrifuge to align asymmetric top SO$_2$ molecules by adiabatically spinning their most polarizable O-O axis. The effective centrifugal potential in the rotating frame confines sulfur atoms to the plane of the laser-induced rotation, leading to the planar molecular alignment which persists after the molecules are released from the centrifuge. Periodic appearance of the full three-dimensional alignment, typically observed only with linear and symmetric top molecules, is also detected. Together with strong in-plane centrifugal forces, which bend the molecules by up to 10 degrees, permanent field-free alignment offers new ways of controlling molecules with laser light.

Aligning the axes of gas-phase molecules in the laboratory frame has long been recognized as a powerful instrument in the growing number of areas of molecular science. For recent reviews on the impact of molecular alignment on the molecular dynamics, interactions and spectroscopy, see Refs.1–3. Today, linear and symmetric top molecules are routinely aligned in one dimension with a single laser pulse, either long (adiabatic) or short (non-adiabatic) on the time scale of the rotational period, interacting with the induced dipole moment of a molecule[4–6]. Aligning the frame of asymmetric top molecules in three dimensions requires more sophisticated methods, capable of controlling the rotation of a molecule around all three of its distinct rotational axes (for recent reviews, see[7, 8]). Both adiabatic[9, 10] and non-adiabatic[11–15] excitation schemes, as well as their combinations[16, 17], have been used for the three-dimensional alignment (3DA) of asymmetric rotors.

Adiabatic approaches excel in producing permanent molecular alignment, but only in the presence of a strong laser field, which is often undesirable. Field-free 3DA (FF3DA) have been achieved by means of the non-adiabatic excitation with a single elliptically polarized pulse[13] or a series of pulses[12, 15]. However, unlike the case of symmetric molecules, where the aligned state is created promptly after the laser pulse and then periodically revives in time, the dynamics of asymmetric rotors exhibit only partial revivals with incommensurate frequencies[18–20]. As a result, the degree of the prompt post-pulse FF3DA is not only limited[13], but is also very sensitive to the field ellipticity and strength[19]. Owing to the same complex aperiodic dynamics, enhancing 3DA with consecutive rotational kicks is inefficient for light molecules like SO$_2$[14], and even for heavier rotors, establishing the optimal timing and ellipticity of pulses is not straightforward and may require experiments with feedback-loop based optimization algorithms[15].

In this work, we demonstrate a new approach to aligning asymmetric top molecules with non-resonant laser pulses. Our method combines the robustness of an adiabatic alignment with field-free conditions of the final aligned state. It is based on the accelerated spinning of molecules with an optical centrifuge - an intense laser pulse, whose linear polarization rotates with gradually increasing angular frequency[21, 22]. Optical centrifuge has recently been used for reaching extreme rotational states, known as molecular “superrotors”[23, 24]. High degree of planar alignment has been demonstrated in the ensembles of centrifuged linear molecules[25]. Here, we extend this technique to the adiabatic alignment of asymmetric rotors.

The essence of our method is illustrated in Fig. 1. The leading edge of the centrifuge (left plane) adiabatically
aligns the molecular axis of maximum polarizability (a axis of SO₂, parallel to the O-O bond) along the field direction. As the rotational frequency ω increases, slowly emerging centrifugal forces in the rotating frame of reference pull the sulfur atom into the plane of rotation, so as to minimize the effective potential $V_{eff} = -\frac{1}{2}I\omega^2$ by maximizing the molecular moment of inertia $I$ around the rotation axis.

To observe the field-free rotational dynamics of the centrifuged SO₂ molecules, we employed the technique of velocity map imaging (VMI) in the similar fashion to that described in our previous work[20]. Briefly, a supersonic jet of helium-seeded sulfur dioxide is exposed to the field of an optical centrifuge between the plates of a time-of-flight mass spectrometer. Ion fragments are collected on a microchannel plate detector (MCP) with a phosphorus screen. To determine the in-plane angular distribution of molecules, an opaque mask with a pinhole in the center is placed on top of the screen, with a photomultiplier tube detector (PMT) behind it (see text for details). (b,c) Images of S³⁺ and SO²⁺ fragments originated from the rotationally cold and centrifuged molecules, respectively.

Gating the MCP voltage for the arrival of either S³⁺ or SO²⁺ ions, we recorded the corresponding VMI images obtained with linear probe polarization, normal to the plane of the MCP. Due to the symmetry of SO₂, the recoil momenta of both species lie in the O-S-O plane of the fragmented molecule and, therefore, define unambiguously the molecular plane at the time of explosion. Without the centrifuge, the observed images exhibited an axial symmetry, expected for the spherically symmetric molecular distribution (Fig. 2(b)). As we turned the centrifuge on, both images collapsed to the plane of the laser-induced rotation, as shown in Fig. 2(c). The simultaneous collapse of the two distributions for both ion fragments indicates strong planar alignment of SO₂ molecules.

We studied the rotational dynamics of aligned molecules within the rotation plane using circularly polarized probe pulses to ensure an isotropic in-plane ionization probability. The in-plane angular distribution of centrifuged molecules was measured as a function of the delay time between the end of the centrifuge pulse and the probe-induced Coulomb explosion. Similarly to our previous work[20], the distribution was determined by recording the ion signal at a single location on the MCP detector (here, in the center of the phosphorous screen) as a function of the release angle of the centrifuge, $\theta_{rel}$ (see Fig. 2(a)). The latter was found in a separate cross-correlation setup, described in detail in Ref.[20].

With the MCP voltage gated at the arrival of S³⁺ ions, the detected signal is proportional to the amount of molecules, $f_{\theta_{rel}}(\theta_b \equiv 0)$, with zero orientation angle $\theta_b$ between the reference TOF axis and the molecular $b$ axis (the one bisecting the O-S-O bond angle, Fig. 1). The dependence of this signal on the release angle $\theta_{rel}$ is equivalent to the dependence on $\theta_b$ at a fixed $\theta_{rel} \equiv 0$, i.e. $f_{\theta_{rel}}(0) \equiv f_0(-\theta_b)$. In what follows, we investigate the latter distribution [hereafter referred to as $f(\theta_b)$] as a function of the centrifuge-to-probe delay time.

The observed time dependence of $f(\theta_b)$ is shown Fig. 3(a). Truncating the centrifuge pulse in time enables us to control the final angular frequency of the centrifuged molecules, which in this case was set to $10^{13}$ rad/s. Due to the centrifuge-induced planar alignment, the number of the rotational degrees of freedom of SO₂ molecules is reduced to one and their dynamics becomes periodic, similar to the dynamics of a linear rotor. This periodicity, though not apparent from the coarse two-dimensional scan, is clearly evident from the extracted alignment factor, $\beta_{2D} = (\cos^2 \theta)_{2D} - \frac{1}{2}$ (with $(..)_{2D}$ being the in-plane average), plotted in Fig. 3(b). Each peak corresponds to the field-free three-dimensional alignment of SO₂.

The relatively small degree of the observed FF3DA stems from the adiabatic mechanism of the centrifuge spinning, which results in a low number of quantum rotational states in the excited wave packet. As we have shown in a recent work on linear rotors[20], a small number of participating states gives rise to long windows of classical-like rotation around the time of each revival, with the rotational frequency equal to the final frequency of the centrifuge. The same “stopwatch” rotation was observed here with SO₂ molecules when we performed a fine time scan around any of the alignment peaks, as demonstrated in Fig. 3(c).

As expected for the effectively one-dimensional rota-
tion, the alignment peaks are separated by half the revival period \( T_{\text{rev}} = 2\pi h (d^2 E / dJ^2)^{-1} \), where \( E(J) \) is the rotational energy for a given rotational quantum number \( J \) and \( h \) is the reduced Plank’s constant \[27, 28\]. Using the rigid rotor’s energy spectrum \( E(J) = \frac{\hbar^2}{2I_J} (J+1) \), with \( I \) being the molecular moment of inertia, one finds \( T_{\text{rev}} = 2\pi I / h \). At lower centrifuge frequencies, the experimentally detected revival period of 57 ps corresponds to \( I = 58 \) Å\(^2\) amu in good agreement with the known value for the molecule’s largest moment of inertia (\( I_c \)) around the axis normal to its plane (\( c \)-axis) \[29\]. These revivals, known as C-type transients \[30\] can be attributed to the beating between a few quantum states \( |J, \tau = -J\rangle \), corresponding to the lowest energy for a given \( J \).

At higher angular frequencies, the rising centrifugal forces stretch and bend the molecule, distorting the two S-O bonds and the angle between them. This causes the moment of inertia, and hence the revival period, to increase, as evident from the experimental data in Fig. 4 (blue circles). To describe the effect of the centrifugal distortion on the revival period, we carried out the following classical calculations. For a given rotational state \( J \), we minimized the total energy:

\[
E(J, r_1, r_2, \alpha) = \frac{\hbar^2 J^2}{2I_c(r_1, r_2, \alpha)} + V(r_1, r_2, \alpha),
\]

over the S-O bonds lengths \( r_{1,2} \) and O-S-O angle \( \alpha \). The potential energy surface (PES) \( V \) of SO\(_2\) was expanded in Taylor series up to the forth order in deformations \( \delta x_i = r_1 - r_e, r_2 - r_e, \alpha - \alpha_e \), where \( r_e \) and \( \alpha_e \) are the

values of \( r_{1,2} \) and \( \alpha \) for the molecule at rest:

\[
V(r_1, r_2, \alpha) = V(r_e, r_e, \alpha_e) + \frac{1}{2} \sum_{ij} f_{ij} \delta x_i \delta x_j + \frac{1}{6} \sum_{ijk} f_{ijk} \delta x_i \delta x_j \delta x_k + \frac{1}{24} \sum_{ijkl} f_{ijkl} \delta x_i \delta x_j \delta x_k \delta x_l,
\]

with the corresponding force constants \( f \) taken from Ref.\[31\]. We then determined the classical angular velocity and the revival period for a given \( J \) as

\[
\omega(J) = \left[ E(J + 1) - E(J) \right] / h
\]

and

\[
T_{\text{rev}} = 2\pi h \left[ E(J - 1) - 2E(J) + E(J + 1) \right]^{-1},
\]

respectively. The results of these calculations are shown in Fig. 4. Expanding PES to second order in deformations \( \delta x_i \) failed to explain the experimental observations at frequencies higher than \( 3 \times 10^{13} \) rad/s (dashed line). The quartic expansion, on the other hand, proved sufficient (solid line). At the highest achieved rotational frequencies of \( 4.4 \times 10^{13} \) rad/s, the calculated bending angle and bond stretching reached 10° and 10 nm, respectively. Both bonds were found to stretch by an equal amount, as could be anticipated from the symmetry of the system.

In summary, we demonstrated and studied a new mechanism of field-free alignment of asymmetric top
molecules with an optical centrifuge. An intuitive classical picture has been presented to explain the observed behavior in the gas of sulfur dioxide. Owing to the adiabaticity of the centrifuge spinning, it leaves SO$_2$ rotating with its O-S-O plane aligned with the plane of rotation long after the excitation pulse is gone. This planar alignment reduces complex rotational dynamics of an asymmetric top to that of a simple linear rotor. Similarly to the latter, centrifuged SO$_2$ molecules exhibit periodic revivals of the transient field-free three-dimensional alignment. The observed FF3DA stems from the slight deviation of the centrifuge action from fully adiabatic. To enhance the degree of the three-dimensional alignment, one could add a short non-adiabatic rotational kick in the plane of the centrifuge-induced rotation. By measuring the revival period as a function of the rotational frequency, we examined the centrifugal distortion of SO$_2$. At extreme levels of rotational excitation, available with an optical centrifuge, the molecule bends by up to ten degrees. Both the planar alignment and the tuneable centrifugal bending add to the arsenal of laser-based tools for controlling molecular dynamics.

This research has been supported by the grants from CFI, BCKDF and NSERC and carried out under the auspices of the UBC Center for Research on Ultra-Cold Systems (CRUCS).
