Effect of Structural Parameters on the Relative Contact Area for Ideal, Anisotropic, and Correlated Random Roughness

Yunong Zhou and Martin H. Müser*

Lehrstuhl für Materialsimulation, Department of Materials Science and Engineering, Saarland University, Saarbrücken, Germany

The relative contact area between an initially flat, adhesion- and frictionless, linearly elastic body and a variety of rough, rigid counterbodies is studied using Green’s function molecular dynamics. The indenter’s height profiles range from ideal random roughness through roughness with a moderate amount of correlation to periodically repeated, single-asperity indenters having perfect phase coherence. At small reduced pressures, $p^* \equiv p/(E^*\bar{g}) \ll 1$, sufficiently large systems are consistent with a linear $a_c = \kappa p^*$ relation. Here $p$ is the pressure, $E^*$ is the contact modulus, $\bar{g}$ the root-mean-square height gradient, and $\kappa$ a unitless proportionality coefficient. However, the parameter $\bar{g}$ must be evaluated over the real contact area for the linear relation to hold if the random roughness is correlated or the interfacial dimension reduced. No single unitless structural parameter—including the Nayak parameter—correlates in a significant fashion with $\kappa$.

Keywords: contact mechanics, simulation, theory, random roughness surface, contact area

1. INTRODUCTION

The understanding of how the relative contact area $a_c$ depends on pressure in nominally flat, linearly elastic contacts has made great progress in the past two decades (Persson, 2001; Müser et al., 2017). Many advanced simulation studies support the view that it increases linearly with pressure from non-zero but very small $a_c$ up to $a_c \approx 0.1$, at least in the limiting and much investigated case of randomly rough, self-affine surfaces (Hyun et al., 2004; Campañá and Müser, 2007; Carbone and Bottiglione, 2008; Putignano et al., 2012; Prodanov et al., 2013). The height spectrum $C(q)$ of a self-affine surface obeys power law scaling with the magnitude of the wavevector $q$ over several decades (Majumdar and Tien, 1990; Palasantzas, 1993; Persson, 2014; Jacobs et al., 2017), i.e., $C(q) \propto q^{-2(1+H)}$, where $H$ is called the Hurst exponent. In the limit of ideal random roughness, the phases of Fourier transforms of the surface height are independent random numbers that are uniformly distributed on $(0, 2\pi)$. In this random-phase approximation, linearity between contact area and load can be rationalized with Persson’s contact mechanics theory (Persson, 2001; Persson et al., 2004), which, in addition to predicting the area-load relation reasonably well, finds a highly accurate pressure-dependence of the interfacial stiffness along with accurate distribution functions of the interfacial separation (Lorenz and Persson, 2008; Almqvist et al., 2011; Campañá et al., 2011; Dapp et al., 2012; Prodanov et al., 2013; Afferrante et al., 2018) and correct spatial stress correlations (Campañá et al., 2008; Persson, 2008), none of which bearing-area models are able to achieve.
While it is sometimes argued that there must be a rigorous linear relation between contact area and load for random surfaces (in the thermodynamic limit), there are several indications for this linearity not to be strict. When the load is so small that contact is made only in a more-or-less connected patch near the highest point, relations for randomly rough surfaces may no longer hold (Pohrt et al., 2012). This, however, can be rationalized as a finite-size effect and be accounted for in Persson theory (Pastewka et al., 2013). However, even when several asperities in contact, deviations from linearity had been noted for Yastrebov et al. (2015). Unfortunately, their calculations were conducted at an essentially fixed ratio of system size and short-wavelength cutoff (with varying roll-off wavelengths) so that small logarithmic corrections to linear relations between contact area and load may not be particularly telling. So far, the strongest support for deviations from linearity were reported in two carefully conducted simulation studies by Nicola and coworkers (van Dokkum et al., 2018; Salehani et al., 2020). They found quite remarkable logarithmic corrections to linear laws in large, one-dimensional adhesionless contacts (van Dokkum et al., 2018) as well as clearly sublinear scaling for two-dimensional, adhesive surfaces (Salehani et al., 2020). However, the latter may have been in a regime with non-negligible adhesive hysteresis, in which case non-linearity between \( \kappa \) and \( p \) is unavoidable. Thus, even these two latter works do not explicitly challenge the view that a linear dependence of contact area on load is an excellent approximation for linearly elastic, sufficiently large, two-dimensional elastic bodies squeezed against a randomly rough, non-adhesive indenter.

An unsolved question is why different Hurst exponents lead to slightly different proportionality coefficients in the equation

\[
\alpha = \frac{\kappa p}{E^* \bar{g}} \tag{1}
\]

where \( p \) is the nominal contact pressure, \( E^* \) the contact modulus, and \( \bar{g} \) the root-mean-square height gradient. Yastrebov et al. (2015) found that the proportionality coefficient \( \kappa \) correlates with the Nayak parameter (Nayak, 1971), \( \Phi_N \) at fixed \( p^* \). As we will argue in this work, \( \Phi_N \) can be seen as the lowest-order unitless, scalar parameter describing a surface topography other than \( \bar{g} \), however, only if the random-phase approximation (rpa) is satisfied. The Nayak parameter is mentioned in many contact-mechanics studies. However, none of them that we are aware of and that claim the proportionality coefficient \( \kappa \) to depend on the Nayak parameter has the numerical sophistication of Yastrebov et al.’s works (Yastrebov et al., 2015, 2017). Nonetheless, they only addressed surfaces with ideal random roughness, i.e., surfaces obeying the rpa, and, as already mentioned above, the ratio of system size and short-wavelength cutoff was kept in a relatively narrow range. Therefore, the Nayak parameter may merely have strongly correlated with other, relevant (stochastic) quantifiers, but not have causally determined the \( \kappa(H) \) dependence.

In fact when leaving the realm of ideally rough surfaces, it does not appear plausible that the Nayak parameter strongly affects \( \kappa \). To see why consider the exact solution to a contact problem (no friction, no adhesion, small-slope approximation) between an initially smooth, linearly elastic manifold squeezed down against a rough, rigid substrate fixed in space. In a thought experiment, modify the substrate’s height profile in the non-contact zones such that all moved points remain below the elastic body. Its equilibrium displacement field and contact points at this and smaller pressures will be the same as for the original substrate, however, the Nayak parameter can have changed by orders of magnitude between the original and the modified indenter. In another thought experiment, consider an indenter with blunt peaks (facing the elastic body) and steep valleys. At a given load, it will have a relatively large contact area. If the indenter’s height profile is flipped around, the Nayak parameter remains the same but now the contact area is strongly diminished as the elastic body is now in contact with sharp peaks. Thus, in one thought experiment, the Nayak parameter changed its value significantly, while the contact area remained unaffected. In the other one, the situation reversed: the contact area changed while the Nayak parameter didn’t. For these reasons, there can be scarcely a broadly applicable correlation between contact area and Nayak parameter, at least once the random-phase approximation has been abandoned.

The two thought experiments reveal that relevant stochastic topographic quantifiers may only depend on functions that are defined in the true contact zones. As desired, such a quantifier would remain unaffected in the first thought experiment when \( \alpha \) does not change, while both would adopt new values in the second thought experiment. Dimensional analysis of the specified contact problem reveals that the root-mean-square gradient plays a central role for the contact area, even in the absence of the random-phase approximation (Prodanov et al., 2013). In fact, one of us (Müser, 2017) demonstrated that Equation (1) also holds for indenters having a harmonic height profile (asperity height decreases as a powerlaw with distance from a symmetry axis) if \( \bar{g} \) is averaged over the true contact area. In this case, \( \alpha = \kappa \) no longer strictly linear in \( p \) since \( \bar{g} \) is a function of load or pressure. Similarly, line contacts between two-dimensional solids were found to obey Equation (1) but only when \( \bar{g} \) was averaged over the true contact (van Dokkum et al., 2018). Thus, the effective \( \kappa \) is a function of the smoothness of the indenter tip, where smoothness would be defined by the functional form of the indents rather than by numerical prefactors.

In this work, we investigate what structural parameters affect the proportionality coefficient \( \kappa \), or more generally, the area-pressure relation. Toward this end, we study the contact mechanics of height profiles with anisotropy and with phase correlation in the Fourier transforms of the height profiles. This correlation is realized by warping rpa height profiles such that peaks are smoothed and valleys are roughened or vice versa, whereby the rpa is destroyed. Anisotropy will also be considered. We then explore to what extent the results on relative contact area correlate with unitless scalar parameters describing the topographic features of the surfaces. These parameters include the Nayak parameter but also a variety of other parameters, which take constant values for rpa surfaces but not for surfaces with correlated (random) roughness.

The remainder of this paper is organized as follows: Model and method are introduced in section 2. The theory is introduced...
in section 3, which includes the systematic construction of topographic order parameters beyond the Nayak parameter. Results are presented in section 4, while conclusions are drawn in section 5.

2. MODEL AND METHOD

As mentioned in the introduction, we are concerned with contacts between an initially flat, linearly elastic body in frictionless contact with a rigid, rough counterface indenting from below. Interactions between the two bodies consist of a non-overlap constraint. This model has been used extensively since Hertz.

The contact problem is solved with Green’s function molecular dynamics (GFMD), which is a frequently employed and described boundary-value method (Campaná and Müser, 2006; Pastewka et al., 2012; Kajita, 2016; van Dokkum and Nicola, 2019). Here we use it in the so-called FIRE-GFMD variant (Zhou et al., 2019).

Most surfaces simulated in this work are randomly rough. The default or rather starting surfaces have the isotropic, self-affine roughness described in the introduction. In addition, it is assumed that ideal self-affine scaling only exists for wave vectors \( q_r \leq q \leq q_s \), where \( q_r \) is the roll-off wave vector and \( q_s \) is the short-wavelength cutoff. Thus, the used spectra are

\[
C(q) = C(q_r) \times \begin{cases} f_{\text{roll}}(q/q_r)^{-2(1+H)} & \text{if } q < q_r \\ 0 & \text{else} \end{cases}
\]

where \( f_{\text{roll}} \) is a Boolean variable, which takes the value of one if true and of zero if false. \( f_{\text{roll}} \) is false by default and only set to true when mentioned explicitly. Thus, by default, \( \lambda_r = 2\pi/q_r \) plays the role of a long wavelength cutoff rather than a roll-off. In almost all cases, the linear dimension of the simulation cell \( L \) is still chosen larger than \( \lambda_r \) in order to average implicitly over different random realizations, which can become relevant for large Hurst exponents at small relative contact areas.

The elastic body is discretized into elements having a linear dimension \( \Delta a \), which is sufficiently small compared to \( \pi/q_r \) in order for the continuum limit to be reached. In fact, different discretizations are considered and results for all observables are extrapolated to the continuum limit \( \epsilon_c = \Delta a/\lambda_r \to 0 \), using a Richardson extrapolation as described in Prodanov et al. (2013). For the contact area, we find a linear dependence in \( \epsilon_c \) of the continuum corrections rather than the previously identified \( \epsilon_c^{2/3} \) dependence (Campaná and Müser, 2007; Prodanov et al., 2013).

Unfortunately, we no longer posses the old configuration files so that analyzing the origin of the discrepancy cannot be clarified. While our GFMD code has been rewritten twice after the original single-authored code by Campana (version 2 by Müser, Dapp, and Prodanov while version 3 was by Müser with Zhou and Wang), we now find a linear \( a(\epsilon_c) \) scaling even when using version 2, which was used, for example, in the contact-mechanics challenge. Although, corrections turn out differently than before, the extrapolated values between old and new results matched whenever tested.

For the so-called fractal correction, i.e., the excess contact area arising due to the ratio \( \epsilon_f = \lambda_s/\lambda_r \) being finite, we also find different scaling than before (Prodanov et al., 2013), i.e., the exponent \( \alpha_f \) of the correction \( \epsilon_f^\alpha_f \) is found to vary between zero (implying approximately logarithmic corrections) and unity. Precise values are difficult to determine due to stochastic scatter. One reason for why we no longer find a unique value for \( \alpha_f \) is that we now consider contact areas in the continuum limit before exploring the limit \( \epsilon_f \to 0 \). However, since we find \( \alpha_f \) to be always equal or less to unity, extrapolation with \( \alpha_f = 1 \) from finite \( \epsilon_f \) to zero should never result in an overcorrection.

Deviations from isotropy are realized by using an effective “Peklenik” wavenumber

\[
q_p = \left( \frac{\gamma^2 q_r^2 + q_f^2 /\gamma^2}{\sqrt{q_r^2 + 1/\gamma^2}} \right)^{1/2}
\]

as the variable in the height spectrum rather than the true wave number \( q \). The Peklenik parameter satisfies \( 0 < q_p < \infty \). Surfaces are stochastically isotropic if \( q_p = 1 \). Anisotropy increases with increasing \( (\ln q_p)^2 \). The such produced height profiles reveal preferred directions or “grooves” in Figure 1, which makes them somewhat more similar to scratched surfaces than topographies with isotropic random roughness.

Phase coherence can be destroyed through a warping transformation. A warped height is defined by

\[
h_w = \begin{cases} h_{\text{min}} + (h - h_{\text{min}}) \left( \frac{h-h_{\text{min}}}{h_{\text{max}}-h_{\text{min}}} \right)^w & \text{if } w \geq 0 \\ h_{\text{max}} - (h_{\text{max}} - h) \left( \frac{h_{\text{max}}-h}{h_{\text{max}}-h_{\text{min}}} \right)^{1-w} & \text{else} \end{cases}
\]

where \( h_{\text{min}} \leq \text{Min} \{h(r)\} \) and \( h_{\text{max}} \geq \text{Max} \{h(r)\} \). Here \( h \) indicates the height of the original (rpa) height profile at a given position \( r \) and \( h_w \) is the height at a given location of the warped surface. At \( w = 0 \), height profiles remain unchanged. For \( w > 0 \), peaks are blunted and valleys sharpened, while the opposite is achieved with \( w < 0 \), as can be seen in the cross-section of the height-profile shown in Figure 2. In the current study, \( h_{\text{min}} = 2\text{Min}[h(r)] \) and \( h_{\text{max}} = 2\text{Max}[h(r)] \) were used.

Phase correlation through our warping procedure is reflected by the observation that the height histograms are systematically skewed for \( w \neq 0 \). In contrast, the height histograms of rpa surfaces are symmetric, except for finite-size effects, because each height profile has the same likelihood to occur as its mirror image in which valleys turn to peaks and vice versa. In addition, the expectation value of the root-mean-square gradient changes with height, i.e., it is much reduced in the blunted parts of the surface compared to the roughened parts. In contrast, for (sufficiently large) rpa surfaces, \( \dot{g} \) is independent of the height, except near the highest and lowest heights in a finite sample. In future topographic determinations of random surfaces with correlation, it would be very interesting to know to what extent the rms-height gradient changes with height. This would probably constitute an important quantity to be targeted.
for computer-generated surfaces. To mimic scratched surfaces realistically, it will probably be required to assume a scale or \( q \)-dependent Peklenik parameter (Candela et al., 2011) in addition to warping and to consider additional refinements. However, our impression is that the \( w = 2 \) surface already contains some features of polished surfaces, i.e., relatively deep valleys and smoothed tops.

In principle, it would have also been possible to consider phase correlation by limiting the values of the phases of \( \tilde{h}(q) \) to a range \( -\varphi_m \leq \varphi \leq \varphi_m \) defined by a minimum/maximum allowed phase \( \varphi_m \) for the phases of all \( \tilde{h}(q) \), while keeping the height spectra \( C(q) \) unchanged. We found this method not to be helpful, because it lead to indenters with sharp thorns. In the limit of \( \varphi_m \rightarrow 0 \), essentially single-point indenters are obtained. Rather than investigating those, we will consider indenters with harmonic height profiles satisfying

\[
h(r) = \frac{R}{n} \left( \frac{r}{R} \right)^n, \tag{5}
\]

where \( R \) is of unit length, while \( r \) is the in-plane distance of a point from the (closest) symmetry axis of an individual indenter, which we place into the center-of-mass of the simulation cell. The values of \( n \) used in this study were restricted to \( n = 1.5 \) (sharp indenter), \( n = 2 \) (Hertzian geometry), and \( n = 4 \) (blunt indenter). Analytical solution for stress and displacement fields (in the contact area and its vicinity) and thus for the dependence of contact area on load are known when the contact radii are negligibly small compared to the linear dimension of the simulation cell.
3. THEORY

3.1. Phenomenological Generalization of Persson Theory

Persson theory for linear elastic contacts between ideally randomly rough surfaces predicts a relative contact area of

$$a_r = \text{erf} \left( \sqrt{2} p_0 / E^* \bar{g} \right), \quad (6)$$

where $\bar{g}$ is the root-mean-square height gradient averaged over the entire surface, i.e.,

$$\bar{g}^2 = \int d^2 q C(q) q^2,$$  

which is the expression in the derivation of Persson theory.

One of us noticed that Equation (6) also holds for smooth indenters with harmonic height profiles if $\bar{g}$ is replaced with $\bar{g}_c$, where the latter is not determined over $\bar{g}$ the entire surface but only over the true contact. Thus, the range of applicability of Equation (6) appears to extend when re-expressing it through

$$a_r = \text{erf} \left( \sqrt{\pi} \kappa_c p_c^*/2 \right), \quad (8)$$

where $\kappa_c$ is the proportionality coefficient between relative contact area and the reduced pressure defined by $p_c^* = p_0 / (E^* \bar{g}_c)$. When omitting the index "c" in $\kappa_c$, we mean to refer to the proportionality coefficient when the reduced pressure is normalized to $\bar{g}$ rather than to $\bar{g}_c$.

In fact, when taking Persson theory literally, it does ask the question how the rms-height changes in a given point of contact (described using a small resolution of the surface topography) when short-wavelength roughness is added to the description of the contact problem. Using the full spectrum to estimate this increase in rms-roughness can be seen as an approximation, which might be possible to correct in future work. Some possibilities are discussed in the conclusions.

The standard Persson theory predicts a value of $\kappa = \sqrt{8/\pi} \approx 1.596$. In the formulation of the theory, it appears to us as if no distinction is made—or must be made—between $\kappa$ and $\kappa_c$, at least as long as pressures lie in a range in which $a_r \propto p$, that is, if $p$ is sufficiently large for contact to spread out over clearly disconnected contact patches but still small enough so that $a_r$ is less than, say, 0.05. Careful simulations of sufficiently large systems find a relatively weak dependence of $\kappa$ on the Hurst roughness exponent, e.g., $\kappa(H \approx 0.8) \gtrsim 2$ and $\kappa(H \approx 0.3) \gtrsim 2$. (Hyun et al., 2004; Campaña and Müsser, 2007; Hyun and Robbins, 2007; Putignano et al., 2012; Prodanov et al., 2013; Afferrante et al., 2018). Analytical results for the Hertz contact result in $\kappa_c \approx 1.666$, see also Equation (28) and the more detailed discussion of periodically repeated, smooth indenters in section 4.5.

3.2. Dimensionless Parameters: Nayak and Beyond

Since the relative contact area is a number, it can only be a function of other unitless parameters ($p^*$, $\Phi_1$, $\Phi_2$, ... ) itself, where $p^*$ is a reduced pressure, e.g., $p/(E^* \bar{g})$. Moreover, each variable in the set $\{\Phi\}$ must obey the law of dimensional analysis. Specifically, they must remain invariant under the scaling transformation $r \rightarrow s \cdot r$ and $z \rightarrow t \cdot z$, since the relation $a_{rel} = a_{rel}(p/E^* \bar{g})$ already reflects the correct dependencies on $s$ and $t$ (Prodanov et al., 2013). Moreover, real contact is destroyed predominantly due to roughness at small wavelengths. Thus, the $\Phi_i$ should not depend on parameters that are defined exclusively by parameters from the height-distribution also known as Abbott Feierstone curve.

Before constructing the respective unitless parameters, it is in place to discuss the square-gradient term. When determining $\bar{g}$ over a periodically repeated contact, $\langle (\nabla h)^2 \rangle$ is identical to $-\langle \delta h \Delta h \rangle$, as can be seen by integration in parts. However, this equality no longer holds for partial contact. Defining

$$\langle \bar{g}_c^2 \rangle = -\langle \delta h \Delta h \rangle_c.$$

the dependence of $a_{rel}$ on parameters depending on height profiles in the contact then becomes

$$a_{rel} = a_{rel}(p/E^* \bar{g}_c, \bar{g}_c, \{\Phi_i\}).$$

Ultimately, $a_{rel}$ is a functional of the height topography. As such, there should exist a dependence of $a_{rel}$ that does not necessitate parameters averaged over the real contact. However, those might necessitate non-local terms, or, alternatively, high-order derivatives of $h(r)$. The latter may not be well defined when the surface profile or its (higher-order) derivatives are not well-defined, as is the case, for example, for a conical indenter. Thus, the following discussion assumes surface height profiles to be smooth and "well behaved."

For the construction of relevant parameters, it is useful to keep in mind three symmetry relations. First, a mirror inversion ($r \rightarrow -r$) leaves the contact area unchanged. This is why each derivative with respect to a spatial coordinate must appear an even number of times in the construction of an invariant. Second, each measure should be rotationally invariant and reduce to a scalar. This is automatically achieved when representing derivatives with the Einstein summation convention, which requires every index (enumerating an in-plane coordinate) occurring twice in a product to be summed over. To use it effectively, we use it jointly with the index notation, in which case $h_{\alpha \alpha}^2$ indicates the square-height gradient $\langle \nabla h \cdot (\nabla h) \rangle$ and $h_{\alpha \alpha}$ the Laplacian $\Delta h$. However, $\bar{g}$ will keep indicating the rms height gradient $\langle \delta h \rangle_{\alpha \alpha}^2$. Third, the invariants may not change on a rigid, vertical translation of the surface $h(r) \rightarrow h(r) + h_0$. This is why only $\delta h = h - \langle h \rangle$ can appear in the invariants. The lowest-order invariant obeying these rules that we could identify are given by

$$\Phi_1 = \frac{\langle \delta h h_{\gamma \alpha}^2 \rangle}{\sqrt{\langle h_{\alpha \alpha}^{\gamma \gamma} \rangle}}, \quad (11)$$

$$\Phi_2 = \frac{-\langle \delta h^2 h_{\alpha \alpha} \rangle}{2 \sqrt{\langle h_{\alpha \alpha}^{\gamma \gamma} \rangle}}, \quad (12)$$

$$\Phi_3 = \frac{-\langle \delta h^2 \rangle_{\alpha \alpha}}{2 \sqrt{\langle h_{\alpha \alpha}^{\gamma \gamma} \rangle}}.$$

where $\delta h = h - \langle h \rangle$. These expressions are dimensionless in the spirit of the selected scaling transformation.
Before constructing the next parameters, the allowed values for the parameter $\Phi_1$ to $\Phi_3$ will be discussed. $\Phi_1$ and $\Phi_2$ are identical when averaged over a periodically repeated surfaces (as can be seen again by integration in parts) but not when they are determined over partial contact, in which case the index “c” would be added. For periodically repeated surfaces, the parameter $\Phi_3$ is automatically identical to zero but generally different from zero when averaged over partial contact. This is because the mean curvature disappears for a periodically repeated surface, while the curvature must average to a negative number for partial contact (assuming the elastic body indents the profile from above).

The values of $\Phi_1$ and $\Phi_2$ averaged over a single rpa surface may be finite. However, averaging these means over various disorder realization will make them appear, as any surface realization will make them disappear, as any surface may be finite. However, averaging these means over various surface realizations. Table 1 contains our conclusions on each parameter constructed in this work.

Additional parameters in which numerator and denominator are second order in the derivative but higher order in $h$ can be constructed. They will be considered up to the lowest order needed beyond the rms-height gradient, in which the parameters do not disappear in case of the random-phase approximation. This includes the parameters

$$\Phi_4 = \frac{\langle h^2 \rangle h_{\alpha\alpha}}{\langle h^2 \rangle g^2} \tag{14}$$

$$\Phi_5 = \frac{-\langle h^3 h_{\alpha\alpha} \rangle}{3 \langle h^2 \rangle g^2} \tag{15}$$

For rpa-surfaces, $\Phi_4$ is automatically equal to unity and for all periodically repeated surfaces, $\Phi_4 = \Phi_5$.

Finally, we consider parameters in which the order of the derivatives is increased from two to four while the order in the height is kept as small as possible. Three of quite a few resulting (irreducible) possibilities are

$$\Phi_6 = \frac{1}{g^2} \langle h^2 \rangle h_{\alpha\alpha} h_{\beta\beta} \tag{16}$$

$$\Phi_7 = \frac{2}{3g^4} \langle h^2 \rangle h_{\alpha\alpha} h_{\beta\beta} \tag{17}$$

$$\Phi_8 = \frac{1}{g^4} \left( \langle h^2 \rangle \langle h^2 \rangle - 3 \langle h^2 \rangle \langle h^2 \rangle + \langle h_{\alpha\alpha} h_{\beta\beta} \rangle \right) \tag{18}$$

$$\Phi_9 = \frac{2}{g^4} \langle h_{\alpha\beta} h_{\gamma\delta} - \frac{1}{2} \langle h_{\alpha\beta} \rangle \langle h_{\gamma\delta} \rangle \rangle \tag{19}$$

where $\delta_{\alpha\beta}$ is the Kronecker-delta symbol.

### Table 1

| Parameter | Full prs | rpa | n-rpa |
|-----------|----------|-----|-------|
| $\Phi_1$  | $\epsilon$ | Allowed |       |
| $\Phi_2$  | $\Phi_1$ | $\Phi_1$ |       |
| $\Phi_3$  | 0        | 0    |       |
| $\Phi_4$  | $1 - \epsilon$ | Allowed |       |
| $\Phi_5$  | $\Phi_4$ | $\Phi_4$ |       |
| $\Phi_6$  | Allowed  | Allowed |       |
| $\Phi_7$  | $\approx \Phi_6$ | Allowed |       |
| $\Phi_8$  | $\epsilon$ | $\epsilon$ |       |
| $\Phi_9$  | $\epsilon$ | $\epsilon$ |       |

The word “allowed” indicates that a finite value is symmetry allowed. The number $\epsilon$ implies that the result averages to zero after an ensemble average over many surface realizations and that it should be small for an individual instantiation.
other parameters of similar or smaller order in height are either identical to zero, or their expectation value is zero, or they strongly correlate with the Nayak parameter.

### 3.3. Evaluation of Fourth-Order Invariants

For (isotropic) randomly rough surfaces, invariants being fourth order in height and fourth order in derivatives are the leading-order, scalar structural parameters that can affect the proportionality coefficient $\kappa$. Of particular interest should be those that—unlike the Nayak parameter—cannot be reduced to products of invariants being second order in height. Yet, the evaluation of fourth-order expressions is commonly done using Wick’s theorem (Wick, 1950), which, applied to the current problem, translates to

$$C_{4l}(q_1, \ldots, q_4) \equiv \left[ \langle h(q_1) h(q_2) h(q_3) h(q_4) \rangle \right]$$

$$\approx \left[ \langle h(q_1) h(q_2) \rangle \langle h(q_3) h(q_4) \rangle \right] + \left[ \langle h(q_1) h(q_3) \rangle \langle h(q_2) h(q_4) \rangle \right] + \left[ \langle h(q_1) h(q_4) \rangle \langle h(q_2) h(q_3) \rangle \right], \quad (20)$$

whereby expectation values of fourth-order expressions are reduced to products of height spectra, since

$$\langle h(q_m) h(q_n) \rangle \propto C(q_m) \delta(q_m + q_n), \quad (21)$$

where $C(q)$ is the height spectrum. Equation (20) is exact for Gaussian random variables of mean zero.

### 4. RESULTS

#### 4.1. On the Accurate Calculation of Contact Area and the Proportionality Coefficient $\kappa$

In Yastrebov et al. (2017), Yastrebov et al. claimed to ensure an unprecedented accuracy in computation of the true contact. If $n_c$ is the number of contact points, $n_{cl}$ the number of contact or rather contact-line points, which are in contact but have at least one non-contact point as nearest neighbor, then the relative contact area was estimated with

$$a_r = \frac{n_c - \alpha n_{cl}}{n_{tot}}, \quad (22)$$

where $n_{tot}$ is the total number of points into which the surface is discretized and $\alpha = (\pi - 1 + \ln 2)/24$.

While we find the proposed correction to be quite useful in order to get an astoundinglly accurate first estimate of the continuum correction for isotropic, rpa surfaces, we believe that it can at best be on par with a properly executed Richardson extrapolation even in that limiting case. The reason is that the numerical coefficient $\alpha \approx 0.11811$ can scarcely be universal even if the special form of writing it as $(\pi - 1 + \ln 2)/24$ might convey a profound mathematical reason for its specific value. To argue why the proposed method cannot surpass a Richardson extrapolation in the asymptotic limit, let us assume that the leading order-correction were indeed proportional to the number of contact-line points within the contact. This number would ultimately scale with $a/\lambda_s$, because the fractal nature of the contact seizures to exist in this limit, so that the contact line acquires the (fractal) dimension of unity, in which case $n_{cl} \propto \lambda_s/a$. This linear scaling of the leading-order corrections to the contact area would be picked up by a Richardson extrapolation and the proportionality coefficient would automatically adjust to the exact value and not only to a value, which is very good but not exact.

The proposed correction scheme can only outperform a Richardson extrapolation if higher-order corrections happened to be incorporated into it. This, in fact, might be the case, as is revealed in Figure 3 by the accurate values from the Yastrebov extrapolation at large $\varepsilon_c$. However, since the exact value $\alpha$ must depend on the specifics of a simulation (artificial geometries can be easily constructed for which $\alpha \equiv 0$ at large loads), it can only be exact in isolated cases of measure zero so that it is generally asymptotically inferior to Richardson. As such, a claim of having provided data with unprecedented accuracy with this method is somewhat hazardous given that previous work used a Richardson extrapolation while employing ratios of $\varepsilon_c = a/\lambda_s$, $\varepsilon_I = \lambda_t/\lambda_s$, and $\varepsilon_T = \lambda_s/L$, which were simultaneously all greater than the data having the purportedly unprecedented accuracy.

The ideas of Yastrebov’s extrapolation can be modified by incorporating the spirit of a Richardson extrapolation into it: if the numbers of contact and contact-line points are known at two different values of $a/\lambda_s$, the parameter $\alpha$ could be adjusted such that the Yastrebov extrapolation gives the same estimate for both discretizations. Asymptotically, this modification leads to an improvement, as can be seen in Figure 3, however, it is usually a disimprovement for $a/\lambda_s \geq 1/4$. To terminate our discussion.
on the Yastrebov extrapolation, we note that we found it to work equally well for warped surfaces as for rpa surfaces and that our final estimates for the relative contact area were always very close, say, within 0.1%, to using a rigorous extrapolation with the value that we obtained with a Yastrebov extrapolation using

\[ \alpha = 0.11 \]  \hspace{1cm} (23)

and a discretization of \( a/\lambda_s \lesssim 1/4 \). This value of \( \alpha \) typically deteriorates the quality of the contact-area estimate for \( a = \lambda_s/2 \) but improves it overall otherwise.

Finally, given that the extrapolation used by Yastrebov and coworkers may lead to different errors at different pressures, the following question remains: What is the origin of their observed logarithmic correction of \( \kappa \) on pressure? Is it the lack of a rigorous extrapolation to the continuum (\( \epsilon_c = a/\lambda_s \to 0 \)), the fractal (\( \epsilon_f = \lambda_s/\lambda_t \to 0 \)), or the thermodynamic (\( \epsilon_t = \lambda_t/L \to 0 \)) limit? Or is it actually true? After all and despite our criticism of their self-appraisal, we see their data to be of similar quality as that of most other cutting-edge works, which had unanimously come to the conclusion of \( \kappa \) acquiring a constant value at small \( p \), but which either simply took the values at the smallest value of \( \epsilon_c \) without further extrapolation or that made Richardson extrapolations, which we can no longer reconstruct. Moreover, one-dimensional systems show robust logarithmic corrections in \( \kappa \) at small \( p \) \cite{vanDokkum2018} even for very large sizes when contact is also made far away from the highest point. (In the preparation of this manuscript, we verified those claims on 1D systems for sizes exceeding \( 2^{20} \) grid points.)

The last limit that needs to be taken to zero is the pressure \( p \to 0 \), i.e., the proportionality coefficient \( \kappa \) should be computed with the smallest possible errors. To do so, we compute \( \kappa \) as a pressure-dependent function through the equation

\[ \kappa = \operatorname{erf} \left( \sqrt{\pi} \kappa p^*/2 \right), \]  \hspace{1cm} (24)

rather than through \( a_t/p^* \) or \( \partial a_t/\partial p^* \), because Equation (24) accounts for some of the low-pressure non linearities, as can be appreciated in Figure 1 of Dapp et al. \cite{Dapp2014}. The zero-pressure limit can only be taken in a meaningful manner in conjunction with a proper size scaling as will be discussed next.

### 4.2. Isotropic rpa Surfaces

#### 4.2.1. Does \( \kappa \) Have a Low-Pressure Limit?

\( \kappa \) cannot have a finite low-pressure limit, if it is defined or computed according to

\[ \kappa = \left( \prod_x \lim_{\epsilon_c \to 0} \lim_{p \to 0} \kappa(p) \right) \]  \hspace{1cm} (25)

where the various limits (defined in the previous section with \( x \) taking the “values” \( c \) for continuum, \( f \) for fractal, and \( t \) for thermodynamic) are taken in arbitrary order. The reason is that for any finite system at exceedingly small pressures, only the highest (meso-scale) asperity is in contact, which (in the realm of continuum-mechanics) will ultimately be Hertzian, in which case \( \kappa \) tends to infinity.

The interesting question is whether \( a_t \) can be proportional to \( p \) over an extended range in pressure with no or negligible logarithmic corrections to the proportionality coefficient \( \kappa \) if both \( \epsilon_f \) are sufficiently small while \( \epsilon_t \) is properly taken to zero at each pressure. Thus, mathematically speaking, we are interested in a limit

\[ \kappa = \lim_{p \to 0} \lim_{\epsilon_{tf} \to 0} \frac{a_t}{p^*}. \]  \hspace{1cm} (26)

since experimental systems, to which simulations should compare, tend to have much larger values of \( \epsilon_{tf} \) than can be realized in a computer simulation. This limit is certainly not approached if the product \( \epsilon_{tf} \) is taken to be effectively constant while having varying discretization errors, as in Yastrebov et al. \cite{Yastrebov2017}. Keeping all but one \( \epsilon_{tf,c} \) constant—as done by Prodanov et al. \cite{Prodanov2013}—is only an unsatisfactory improvement, because the discretization corrections probably decrease as \( \epsilon_t \) decreases due to the increase of the characteristic patch size. The cardinal mistake made by Prodanov et al. \cite{Prodanov2013} was to assume that leading errors to \( \kappa \) are sums of terms \( c_k \epsilon_k \nu_x \) with \( x \in \{c, f, t\} \) and \( 0 < \nu_x \), while they could also be of a more general form and involve, e.g., products of powers of different \( \epsilon_x \).

To explore the question raised at the beginning of the previous paragraph in a somewhat more meaningful way than before, we ran simulations in which \( \epsilon_f \) and/or \( \epsilon_t \) were decreased simultaneously with decreasing pressure \( p \) according to

\[ \epsilon = \epsilon_{ref}(p/p_{ref})^{1/3}. \]  \hspace{1cm} (27)

Results are shown in Figure 4, for which we chose (arbitrarily) \( \epsilon_f = 1/32 \) and \( \epsilon_t = 1/2 \) at a reference pressure of \( p^* = 0.2 \). It reveals that \( \kappa \) increases quite noticeably with decreasing pressure for all three \( H = 0.3 \) systems, while it essentially plateaus for the two \( H = 0.8 \) systems in which \( \epsilon_t \) is decreased as \( p \) decreases. While the \( H = 0.3 \) might also plateau at even smaller \( p^* \), a qualitative difference between \( H = 0.3 \) and \( H = 0.8 \) would remain: The curves in which both \( \epsilon_f \) and \( \epsilon_t \) are decreased with decreasing \( p^* \) lead to small \( \kappa \) for \( H = 0.8 \) but to large \( \kappa \) for \( H = 0.3 \), which become even larger for fixed \( \epsilon_f \).

The reason for the different trends can be potentially linked to the distribution of contact patch areas and the characteristic contact patch size \( A_c \), which we define to be the expected patch size that a randomly picked contact point belongs to. The three \( H = 0.3 \) cases and the \( H = 0.8 \) case with fixed \( \epsilon_f \), all belong to situations, in which the characteristic contact areas are rather small: \( A_c \) increases only logarithmically with \( \epsilon_t \) for \( H < 0.5 \) \cite{Müser2018} so that large patches are not possible, even when \( \epsilon_t \) is small. Likewise, only small contact patches can arise for \( H = 0.8 \) at pressures well below the percolation threshold if \( \epsilon_t \) is fixed to a constant value as large as \( \epsilon_t = 1/32 \). In contrast, large contact patches can arise even at small pressures, if \( \epsilon_t \) is small and \( H > 0.5 \). Large patches are needed for a linear \( a_t(p) \) dependence at small pressures, as can be rationalized qualitatively from bearing-area models.

In order to explore the question further, if \( \kappa \) can have a well-defined limit when being deduced with the meaningful limit defined in Equation (26), we compare the \( \kappa(p) \) relation with two
sets of $\varepsilon_{i,f}$: (i) a small system with $\varepsilon_i = 1$ and $\varepsilon_f = 1/32$ and (ii) a larger system in which both $\varepsilon_i$ and $\varepsilon_f$ were decreased by a factor of four to $\varepsilon_i = 1/4$ and $\varepsilon_f = 1/128$. Figure 5 reveals that the pressure sensitivity of $\kappa$ reduces quite noticeably with increasing system size for $H = 0.8$ but not for $H = 0.3$, which, however, has a relatively minor logarithmic dependence of $\kappa$ on $p^*$ to begin with.

The trends revealed in Figure 5 are consistent with those of Figure 4. Increasing system size, i.e., decreasing simultaneously $\varepsilon_i$ and $\varepsilon_f$, reduces $\kappa$ and its pressure sensitivity for $H = 0.8$ but not for $H = 0.3$. Our trends are also roughly consistent with the observations by Prodanov et al. (2013), who proposed the existence of a well-defined value for $\kappa$ for $H = 0.8$ but not for $H = 0.3$.

While we already speculatively linked the different trends for $H = 0.3$ and $H = 0.8$ to the way how a characteristic contact patch size changes with decreasing $\varepsilon_f$, it remains to be explained why $A_c$ increases only logarithmically with $\varepsilon_f$ for $H < 0.5$ but algebraically for $H > 0.5$. One possibility could be that most of the elastic energy (in full contact) is stored in long-wavelength modes for $H > 0.5$ but in short-wavelength modes for $H < 0.5$. If this argument were true, $H = 0.5$ could be the dividing line for the different types of behaviors. We therefore repeated the analysis shown in Figure 5 for $H = 0.5$. Unfortunately, the results leave us somewhat uncertain. Significantly more work must probably be done to characterize the transition between the different scaling behaviors rigorously.

To conclude this section on the much investigated isotropic, rpa surfaces, we expect $\kappa$ to have a well defined zero-pressure limit, in the sense of Equation (26), which does not depend upon how it is approached. For small Hurst exponents, i.e., for $H > 0.5$, it might not exist and/or it might depend on how $\varepsilon_f \to 0$ is approached, e.g., it could take different values when reaching it with constant $\varepsilon_f/\varepsilon_i$ than with constant $\varepsilon_f/\sqrt{\varepsilon_i}$. At the same time, we somewhat expect that the value of $\kappa \approx 2.5$ predicted by the more sophisticated bearing-area models, such as that by Bush et al. (1975), might provide a (potentially rigorous) upper bound for $\kappa$ when the limit $\varepsilon_i \to 0$ is taken before $\varepsilon_f \to 0$. In this case, the surface roughness on scales exceeding the roll-off wavelength is white noise so that the underlying mean-field model of elasticity might not be detrimental.

### 4.2.2. Effect of Nayak and Related Parameters on $\kappa$

Yastrebov et al. (2017) proposed the proportionality coefficient $\kappa$ to decrease logarithmically with the Nayak parameter, at least for self-affine, rpa surfaces. However, two aspects of this claim and their data strike us as troublesome. First, $\kappa$ is implicitly predicted to become negative for very large Nayak parameters, which is physically meaningless. Second, their data points seem
to be partially inconsistent, e.g., in their Figure 10D, the points \((\Phi_N, \kappa) = (700, 1.93)\) and \((70, 2.05)\) should be moved to \((70, 1.93)\) and \((700, 2.05)\), respectively. The Nayak parameter \(\Phi_N\) would then be consistent not only with our own calculations but also with the values that Yastrebov et al. reported themselves in their Figure 1. Once these two data points are corrected, the logarithmic relation seems to be much less convincing than with improperly plotted data.

To provide an independent test of the extent with which the Nayak parameter affects the proportionality coefficient \(\kappa\), we investigated a broader range of surfaces than before and contrast in light of the observation that one-dimensional surfaces have markedly different dependencies of \(\kappa\) for \(p^*\) alone.

### 4.3. Anisotropic rpa Surfaces

To address the question how anisotropy affects the relative contact area, we repeated the simulations presented in Figure 4 with a Peklenik number of \(\gamma_p = 4\). Results are shown in Figure 7. It can be seen that anisotropy enhances the pressure dependence of \(\kappa\) at fixed values of \(\varepsilon_f\) compared to stochastically isotropic surfaces with \(\gamma_p = 1\). This may not be particularly surprising in light of the observation that one-dimensional surfaces have logarithmic corrections to the \(\kappa(p)\) relation, even for \(H > 0.5\). By using a Peklenik number clearly differing from unity, roughness dominates along one spatial dimension, whereby the spatial dimension can be argued to have been reduced to a certain extent.

Figure 7 also finds that \(\kappa(H = 0.8)\) is not very pressure sensitive when \(\varepsilon_f\) is decreased with pressure so that for macroscopic systems, in which \(\varepsilon_f\) is two to three orders of magnitude smaller than in simulations, the pressure sensitivity is marginally small. However, due to anisotropy, \(\kappa\) is noticeably increased with respect to the isotropic case. When Peklenik numbers differ very much from unity, different laws may apply as the surface's dimensionality has effectively changed from two to one. In the limit of one-dimensional surfaces, the pressure sensitivity of \(\kappa\) at small \(p^*\) has been convincingly established not only for small \(H\) but also for \(H = 0.8\) (van Dokkum et al., 2018).

As a final comment on the non-isotropic rpa surfaces, we note that \(\kappa_c\), whose definition of reduced pressure uses the root-mean-square height gradient \(\bar{g}\) averaged over contact only, has a rather weak dependence on \(p^*\). Values are generally close to 1.8. Interestingly, the ordering of the points are essentially in reverse order compared to the analysis in which \(\bar{g}\) was averaged over entire surfaces.

The smallest \(\kappa_c\) occurs for the smallest Hurst exponent, which can be rationalized as follows: For \(H = 0.3\), roughness exists predominantly at short wavelengths and contact patches are rather small compared to \(H = 0.8\). The coarse-grained, or rotationally averaged height profile of an individual meso-scale asperity is therefore blunter for \(H = 0.8\) (where many valleys are sampled over) than for \(H = 0.3\) (containing essentially only high peaks). Neglecting the fact that contact is more and more partial in such a mesoscale asperity with distance from the highest peak, Equation (28) finds that blunter tips have larger \(\kappa_c\). The extreme limit at small \(p^*\) should be a Hertzian asperity, for which \(\kappa_c \approx 1.666\). The blunter the profile, the larger \(\kappa_c\).
4.4. Isotropic Height-Warped Surfaces

The assumption of the random-phase approximation is subject to the serious and legitimate criticism not only of Persson’s contact mechanics theory but on a large body of simulation studies using ideal, rpa surfaces. Quite a few numerical studies use a Weierstrass profile, which has (perfect) phase correlation, while reproducing a height autocorrelation function (ACF) being similar to experimental ACFs. However, the Weierstrass profile lacks any visual similarity to experimental surfaces as demonstrated in Figure 2 of Müser (2018). We therefore believe that the warping method proposed in section 2, while probably still being far from ideal, reproduces the stochastic properties of correlated surfaces in a significantly more realistic fashion than a Weierstrass-function based height profile.

Figure 8 reveals that the increase of $\kappa$ with decreasing pressure is much accentuated for a positive warping exponent $w$, in which case the peaks of the indenting asperities are flattened compared to the valleys. This times $\kappa(H = 0.8)$ even increases with decreasing $p^*$ when $\epsilon_I$ is reduced with decreasing pressure. However, for the opposite case of $w < 0$ leading to sharp asperities and shallow valleys, $\kappa$ is found to decrease with pressure. This statement also holds in certain pressure ranges, when $\epsilon_I$ is not scaled according to Equation (27) but kept constant.

When defining the root-mean-square height gradient and thus the reduced pressure with respect to the true contact area, $\kappa_c$ turns out yet again to be rather insensitive to the reduced pressure and to be around 1.8 for small $p^*$.

Correlating the respective values of $\kappa_c$ with the structural parameters, which are symmetry-allowed and finite, has remained unsuccessful so far.

4.5. Periodically Repeated Smooth Indenters

When indenters are periodically repeated, each indenter carries the same load. If the linear contact dimension is small compared to the period, that is, at small applied external pressures $p_0$, a similar relation between contact area and load or pressure must be obtained as if the indenter were isolated. As already mentioned in the introduction, it has been noticed recently (Müser, 2017) that the corresponding asymptotic low-pressure relation for periodically repeated indenters with harmonic height profiles can be cast in terms of Equation (8). The prefactor $\kappa_c$ can be calculated analytically, specifically

$$\kappa_c(n) = \sqrt{\frac{\pi}{n} \frac{\Gamma\left(\frac{n}{2} + \frac{3}{2}\right)}{\Gamma\left(\frac{n}{2} + 1\right)},}$$

where $\Gamma(\bullet)$ represent the gamma function. The numerical data shown in Figure 9 confirms the analytical results at low pressures. Errors in the relative contact become noticeable only once $a_r$ exceeds 0.3, but they remain below 25%. The high-pressure asymptotics can also be described reasonably well with Equation (8), however, the value for $\kappa_c$ needs to be decreased. Since the approach to full contact is the quite special case of a conical dimple for the periodically repeated indenters, it will not be investigated any further in this study.

5. DISCUSSIONS AND CONCLUSIONS

In this study, various structural parameters determining the relative contact area $a_r$ in a contact between a rough surface and a linearly elastic counterbody were investigated. The focus was laid on the questions if $a_r$ is linear in pressure $p$ and inversely proportional to the root-mean square height gradient $\tilde{g}$ for small reduced pressures, defined as $p^* = p/(E^*\tilde{g})$, and if yes, what structural parameters determine the proportionality coefficient $\kappa$.

One of the difficulties to determine whether or not $a_r$ is linear in $p^*$ at small $p^*$ is that taking the limit $p^* \rightarrow 0$ properly is not a simple task, because the ratios of roll-off wavelength and system size, $\epsilon_l = \lambda_s/L$ (size scaling), as well as the ratio of short-wavelength cutoff and roll-off wavelength, $\epsilon_I = \lambda_s/\lambda_{rs}$ (fractal scaling), have to be made systematically small. While Prodanov et al. (2013) emphasized the necessity of such a finite-size and fractal scaling, they failed to take that limit properly themselves, as they kept the ratio of linear mesh size and short-wavelength cutoff, $\epsilon_c = a/\lambda_{rs}$, fixed. In this study,
we extrapolated results for a specific surface configuration to $\varepsilon_c$ first and then computed contact area while taking $\varepsilon_t$ and $\varepsilon_f$ to zero simultaneously or by taking $\varepsilon_t$ to zero while keeping $\varepsilon_f$ constant.

The last type of analysis, in which effectively $\varepsilon_c = 0$, while $\varepsilon_t$ is kept constant and $p^*$ is set to a (very) small value, deserves particular attention. When doing so, only a single meso-scale asperity contact (SMAC) will ultimately remain in contact, even when the entire surface is brought into contact at 20% relative contact area, as is implicitly assumed in bearing-area models. However, this is the simplest correction that comes to our mind at this point of time. It is certainly much less tedious to work out than the systematic corrections to Persson theory needed to be made. In all investigated randomly-rough surfaces at small $a_i$ so that (according to Persson theory and simulations presented in this work) $a_i$ turns out larger than in the thermodynamic limit. While Persson theory cannot (yet) be used either to explain why different Hurst exponents lead to different $\kappa$, it does allow deviations of $\kappa(p^*)$ from linearity to be rationalized for both finite systems and surfaces violating the random-phase approximation. The basic version of Persson theory assumes that the elastic body “feels” the full root-mean-square gradient (averaged over the entire surface) as soon as the elastic body hits the rough substrate. However, for any finite surface, a certain fraction must be in contact before the root-mean-square gradient and other stochastic parameters, such as the kurtosis, approach their “true” mean values. While this fraction decreases with system size, $\tilde{g}$ (typically) remains below its asymptotic value for finite rpa surfaces at small $a_i$ so that (according to Persson theory and simulations presented in this work) $a_i$ turns out larger than in the thermodynamic limit. A possible correction of Persson theory for this case could be to identify the rms-gradient of the $a_i \times 100\%$ top- (or bottom) most heights and use this value to determine the reduced pressure $p_{c}^{*}$, which would then satisfy Equation (8) reasonably well. To some extent, this would constitute a somewhat dissatisfactory compromise between Persson theory and bearing-area models, since it is not the top- (or bottom) most, say, 20% of the peaks that are in contact at 20% relative contact area, as is implicitly assumed in bearing-area models. However, this is the simplest correction that comes to our mind at this point of time. It is certainly much less tedious to work out than the systematic corrections to Persson theory relying on a cumulant expansion of the short- but finite-range repulsive interactions between indenter and elastic body (Müser, 2008).

In full simulations, $\tilde{g}$ can be averaged over the true contact area and no compromise between bearing-area models and Persson theory needs to be made. In all investigated randomly-rough contacts, we find a close-to-linear relation between $a_i$ and $p_c^*$, i.e., when averaging the rms height gradient only over the true contact even if the original $a_i(p)$ deviates clearly from linearity. In these simulations, we find $\kappa_c$ to lie in the relatively narrow range satisfying $\kappa_c \approx 1.8 \pm 0.1$. This value for $\kappa_c$ is only slightly larger than the value of 1.6 predicted by Persson theory but clearly below the value of 2.5 predicted by BGT (Bush et al., 1975). Thus, the range of validity of Persson theory could be substantially expanded if the approximations of using the full rms-height gradient were replaced with an accurate estimate of the mean rms-height gradient in the true contact.

The discussion in the last paragraph as well as the analysis conducted in the results section of this work reveals already at the present level of rigor that the Nayak parameter $\Phi_N$ has no stringent direct correlation with the proportionality coefficient $\kappa$, which would allow the function $\kappa(p^*,H,\varepsilon_t,\varepsilon_f)$ to be reduced to a smaller number of variables, such as, $\kappa = \kappa(p^*,\Phi_N,\varepsilon_f)$. This in turn emphasizes once more that a rigorous understanding of contact mechanics necessitates a spectral analysis of the height profiles. Knowledge of the Nayak parameter and even more so of simple distribution functions of asperity heights and geometries is unavailing.

While Persson theory cannot (yet) be used either to explain why different Hurst exponents lead to different $\kappa$, it does allow deviations of $\kappa(p^*)$ from linearity to be rationalized for both finite systems and surfaces violating the random-phase approximation. The basic version of Persson theory assumes that the elastic body “feels” the full root-mean-square gradient (averaged over the entire surface) as soon as the elastic body hits the rough substrate. However, for any finite surface, a certain fraction must be in contact before the root-mean-square gradient and other stochastic parameters, such as the kurtosis, approach their “true” mean values. While this fraction decreases with system size, $\tilde{g}$ (typically) remains below its asymptotic value for finite rpa surfaces at small $a_i$ so that (according to Persson theory and simulations presented in this work) $a_i$ turns out larger than in the thermodynamic limit. A possible correction of Persson theory for this case could be to identify the rms-gradient of the $a_i \times 100\%$ top- (or bottom) most heights and use this value to determine the reduced pressure $p_{c}^{*}$, which would then satisfy Equation (8) reasonably well. To some extent, this would constitute a somewhat dissatisfactory compromise between Persson theory and bearing-area models, since it is not the top- (or bottom) most, say, 20% of the peaks that are in contact at 20% relative contact area, as is implicitly assumed in bearing-area models. However, this is the simplest correction that comes to our mind at this point of time. It is certainly much less tedious to work out than the systematic corrections to Persson theory relying on a cumulant expansion of the short- but finite-range repulsive interactions between indenter and elastic body (Müser, 2008).

In full simulations, $\tilde{g}$ can be averaged over the true contact area and no compromise between bearing-area models and Persson theory needs to be made. In all investigated randomly-rough contacts, we find a close-to-linear relation between $a_i$ and $p_{c}^{*}$, i.e., when averaging the rms height gradient only over the true contact even if the original $a_i(p)$ deviates clearly from linearity. In these simulations, we find $\kappa_c$ to lie in the relatively narrow range satisfying $\kappa_c \approx 1.8 \pm 0.1$. This value for $\kappa_c$ is only slightly larger than the value of 1.6 predicted by Persson theory but clearly below the value of 2.5 predicted by BGT (Bush et al., 1975). Thus, the range of validity of Persson theory could be substantially expanded if the approximations of using the full rms-height gradient were replaced with an accurate estimate of the mean rms-height gradient in the true contact.
It is certainly justified to consider many parts of this study to be more of a mathematical exercise rather than an attempt to model any specific real-world problem. And anyone wondering why there has to be yet another paper on $\kappa$ can be assured to have our full sympathy. However, if poorly conducted studies of contact problems lead to the conclusion that a legitimate theory is brought into discredit and these studies receive many citations as evidence for the theory to be flawed, it should be in place to demonstrate that a carefully conducted analysis supports the theory.
