Abstract. – A first-principle continuum-mechanics expression for the rolling friction coefficient is obtained for the rolling motion of a viscoelastic sphere on a hard plane. It relates the friction coefficient to the viscous and elastic constants of the sphere material. The relation obtained refers to the case when the deformation of the sphere $\xi$ is small, the velocity of the sphere $V$ is much less than the speed of sound in the material and when the characteristic time $\xi/V$ is much larger than the dissipative relaxation times of the viscoelastic material. To our knowledge this is the first “first-principle” expression of the rolling friction coefficient which does not contain empirical parameters.

Rolling friction is one of the basic phenomenon men encounters in his everyday life since antediluvian times when the wheel was invented. The phenomenon of rolling friction has been interesting to scientist for a long time. Scientific publications on this subject range back to (at least) 1785 when Vince described systematic experiments to determine the nature of friction laws \textsuperscript{1}, and important scientists dealt with this problem among them O. Reynolds \textsuperscript{2}. The rolling friction is of great importance in engineering and science. From the speed of landslides Huang and Wang \textsuperscript{3} argued that the rolling friction plays an important rôle even in geological processes, for a theoretical consideration see \textsuperscript{4}. For its major importance the phenomenon has been studied intensively by engineers and physicists (e.g. \textsuperscript{5}), however, surprisingly few is known about its basic mechanisms. To our knowledge there is still no “first-principle” expression for the rolling friction coefficient available which relates this coefficient only to the material constants of the rolling body and does not contain empirical parameters.

It has been shown that surface effects like adhesion \textsuperscript{6}, electrostatic interaction \textsuperscript{7}, and other surface properties \textsuperscript{8} might influence the value of the rolling friction coefficient. Theoretically this problem was studied in Ref. \textsuperscript{9} where the authors propose a model of a surface with asperities to mimic friction (see also \textsuperscript{10}). In other studies \textsuperscript{11,12} it was argued that for

Typeset using EURO-TpX
viscoelastic materials “the rolling friction is due very little to surface interactions: the major part is due to deformation losses within the bulk of the material” [1]. Based on this concept the rolling friction coefficient was calculated in [1] where the deformation in the bulk was assumed to be completely plastic; then an empirical coefficient was introduced to account for the retarded recover of the material.

In the present letter we also consider the rolling friction as a phenomenon appearing due to viscous processes in the bulk. We assume that energy losses due to surface effects may be neglected, compared to the viscous dissipation in the bulk. Thus we attribute the effect of rolling friction to viscous dissipation in the material due to time-dependent deformation. We assume that the only role of surface forces is to keep the rolling body from sliding. We use a quasi-static approach [13] and obtain the rolling friction coefficient.

Fig. 1. – Sketch of the rolling sphere, the right figure shows the appearance of the friction momentum: in the front the elastic stress is enhanced by the dissipative stress, while in the rear it is diminished.

Fig. [1] shows a sketch of the sphere of radius \( R \) and mass \( m \) rolling with angular velocity \( \Omega \) which is related to its linear velocity \( V \) as \( V = \Omega R \). The center of the coordinate system \( OXYZ \) coincides with the center of the sphere (moving coordinate system), so that the plane is normal to the \( Z \)-axis and located at \( z_p < 0 \). Within our model we assume that the surface is much harder than the sphere, hence, the surface remains flat in the contact area while the sphere is deformed. Thus the contact area is a circle of radius \( a \). The compression \( \xi = R - |z_p| \) of the sphere causes the displacement field in the bulk of the material \( \vec{u}(\vec{r}, t) \) where \( \vec{r} \) gives the location of the point within the sphere at time \( t \). The displacement field gives rise to a (tensorial) field of deformation \( \vec{\nabla} \circ \vec{u} \), and thus to the elastic part of the stress tensor \( \hat{\sigma}_{el} \) [14]

\[
\hat{\sigma}_{el} = E_1 \left[ \frac{1}{2} \left\{ \vec{\nabla} \circ \vec{u} + \vec{u} \circ \vec{\nabla} \right\} - \frac{1}{3} \hat{I} \vec{\nabla} \cdot \vec{u} \right] + E_2 \hat{I} \vec{\nabla} \cdot \vec{u}.
\]  

(1)

Here, \( \hat{I} \) is the unit tensor and \( E_1 = \frac{Y}{1+\nu} \) and \( E_2 = \frac{Y}{3(1-2\nu)} \) denote the elastic material constants with \( Y \) and \( \nu \) being the Young modulus and the Poisson ratio, respectively. Since the deformation depends on time via the time-dependent field \( \vec{u}(\vec{r}, t) \), the dissipative part of the stress tensor reads

\[
\hat{\sigma}_{dis} = \eta_1 \left[ \frac{1}{2} \left\{ \vec{\nabla} \circ \dot{\vec{u}} + \dot{\vec{u}} \circ \vec{\nabla} \right\} - \frac{1}{3} \hat{I} \vec{\nabla} \cdot \dot{\vec{u}} \right] + \eta_2 \hat{I} \vec{\nabla} \cdot \dot{\vec{u}},
\]  

(2)
where \( \hat{u} \) denotes the time derivative of the displacement field and \( \eta_1 \) and \( \eta_2 \) are the viscous constants of the sphere material \([4]\). The total stress \( \hat{\sigma} \) is a sum of both parts, \( \hat{\sigma} = \hat{\sigma}_{el} + \hat{\sigma}_{dis} \).

The force normal to the plane which acts on the sphere is caused by its own weight \( mg \). It reads

\[
\vec{F} = \int_{S_n} \hat{\sigma} \cdot \vec{n} \, ds = \vec{n} \int \int dx dy \left( \sigma_{zz}^{el} + \sigma_{zz}^{dis} \right) = \vec{n}F_N ,
\]

where \( \vec{n} \) is the (positively directed) unit normal to the plane, \( \sigma_{zz}^{el} \) and \( \sigma_{zz}^{dis} \) are the corresponding components of the stress tensors. The integration is to be performed over the contact circle \( S_n \) on the plane \( z = z_p \). Correspondingly, the torque acting on the sphere with respect to the point \( O' \) at rest (no slipping conditions) is given by

\[
\vec{M} = \int_{S_n} \left( \vec{r} - \vec{r}_{O'} \right) \times (\hat{\sigma} \cdot \vec{n}) \, ds ,
\]

where \( \vec{r}_{O'} = (0, 0, z_p) \). The torque \( \vec{M} \) thus characterizes the rolling friction.

Let the sphere move in \( y \)-direction, \( \vec{V} = (0, V, 0) \), then the angular velocity and the friction torque are directed along the \( x \)-axis, i.e. \( \hat{\Omega} = (-\Omega, 0, 0) \) and \( \hat{M} = (M, 0, 0) \) (see Fig. 1). For this geometry from Eq. (1) follows

\[
M = \int \int dx dy \ y \hat{\sigma}^{zz} (x, y, z = z_p)
\]

The integration in Eq. (1) again is performed over the contact circle.

To perform the calculation of the friction torque one needs the displacement field \( \hat{u}(\vec{r}, t) \) and the field of the displacement velocity \( \hat{u}(\vec{r}, t) \). Generally, to find these quantities is a rather complicated problem. Nevertheless, one can use a quasi-static approximation, provided that the displacement velocities in the bulk are much smaller than the speed of sound in the sphere material and provided the characteristic time of the process of interest, estimated by \( r = \xi/V \), is much larger than the dissipative relaxation times of the material (see \([13]\) for details). This allows to employ for the displacement field \( \hat{u} \) the results of the static problem, i.e. of the Hertz contact problem which refers to a “slow” elastic collision of two spheres \([15]\). In the case considered here one of the spheres (the plane) should have infinite radius. Let \( \vec{u}_{el}(\vec{r}) \) be the solution of this (static) contact problem. It corresponds to the displacement field in a sphere under the compression \( \xi \) (see Fig. 1) if it would be at rest. In the quasi-static approximation the distribution \( \vec{u}_{el}(\vec{r}) \) persists (i.e. it does not change with time) in the coordinate system \( OXYZ \), moving with the velocity \( V \) (with no rotation). In a body-fixed coordinate system \( OXYZ \) (see Fig. 1), which rotates with the angular velocity \( \Omega \) and coincides at some time instant with \( OXYZ \) the displacements distribution is the same as in \( OXYZ \) (i.e. \( \vec{u}_{el}(\vec{r}) \) ), while the displacement velocity distribution follows from the kinematic equation

\[
\hat{u}(\vec{r}) = (\hat{\Omega} \cdot \vec{r} \times \vec{\nabla})\vec{u}_{el}(\vec{r}) = -\Omega (y \partial_z - \partial_y) \vec{u}_{el}(\vec{r})
\]

which relates both coordinate systems; here \( \partial_x = \frac{\partial}{\partial x} \), \( \partial_y = \frac{\partial}{\partial y} \) and \( \partial_z = \frac{\partial}{\partial z} \). The elastic part of the stress tensor is then obtained by substituting \( \vec{u}_{el}(\vec{r}) \) into Eq. (1). This part of the stress tensor corresponds to the static case when no torque acts on the sphere. Therefore, in the quasi-static approximation only the dissipative part of the stress tensor \( \hat{\sigma}_{zz}^{dis} \) should be used in Eq. (1) for the friction torque. Using kinematic Eq. (3) and definitions (1) and (2) one finds for the dissipative part

\[
\hat{\sigma}_{zz}^{dis} = -\Omega \left\{ (y \partial_z - \partial_y) \hat{\sigma}_{zz}^{el} (E_1 \leftrightarrow \eta_1; E_2 \leftrightarrow \eta_2) + 2\hat{\sigma}_{zz}^{el} (E_1 \leftrightarrow (\eta_2 - \eta_1/3); E_2 \leftrightarrow \eta_2) - (2\eta_2 + \eta_1/3)\partial_y u_{el} \right\}.
\]
where \( u_{cl}^z = (u_{cl}^x, u_{cl}^y, u_{cl}^z) \) and \( E_1 \leftrightarrow \eta_1, E_2 \leftrightarrow \eta_2 \), etc.: in the arguments of the elastic stress tensor denote that the elastic constants \( E_1, E_2 \), etc. in Eq. (10) should be replaced by the dissipative constants \( \eta_1, \eta_2 \), etc.

For the case of small compression \( \xi/R \ll 1 \) which is addressed here we estimate the magnitude of different terms in Eq. (10) taken at the plane \( z = z_p \approx -R \), since these values of the stress tensor determine the friction torque (see Eq. (11)). For the diagonal component of the stress tensor one has the known solution for the Hertz contact problem [15, 14].

\[
\sigma_{el}^{zz}(x, y, z_p) = E_1 \partial_z u_{cl}^z + (E_2 - E_1/3) (\partial_x u_{cl}^x + \partial_y u_{cl}^y + \partial_z u_{cl}^z)
\]

\[
= \frac{3 F_N}{2 \pi a b} \sqrt{1 - \frac{x^2}{a^2} - \frac{y^2}{b^2}}.
\]

(8)

where \( a = b = \sqrt{2\xi R} \) is the radius of the contact circle and \( F_N^N \) is the total elastic force, acting by the surface (in normal direction) on the sphere:

\[
F_N^N(\xi) = \frac{2}{3} \left( 1 - \frac{\eta}{2} \right) R^{1/2} \xi^{3/2}.
\]

(9)

From Eq. (8) follows \( \sigma_{el}^{zz} \sim (\xi/R)^{1/2} \) at \( z = z_p \). Applying geometric consideration of the deformation of the sphere one gets \( u_{cl}^x \sim u_{el}^x \sim \xi^{3/2}/R^{1/2} \), \( u_{cl}^y \sim \xi \). The estimates \( \partial_x \sim \partial_y \sim 1/a \sim (R)^{-1/2} \) and \( \partial_z \sim \xi \sim (\xi R)^{-1/2} \) may be obtained too. The expression for \( \partial_z \) follows from the estimates for \( u_{cl}^z \). \( \sigma_{el}^{zz} \) and the definition of \( \sigma_{el}^{zz} \). Finally we find for the deformation

\[
\partial_z u_{cl}^x \sim \partial_y u_{cl}^y \sim \partial_x u_{cl}^z \sim \xi/R \ll (\xi/R)^{1/2}
\]

\[
\partial_z u_{cl}^y \sim \partial_y u_{cl}^x \sim \partial_x u_{cl}^y \sim (\xi/R)^{1/2}
\]

\[
\partial_z u_{cl}^z \sim \partial_y u_{cl}^y \sim \partial_x u_{cl}^z \sim (\xi/R)^{1/2}.
\]

(10)

Eqs. (10) further yield \( \sigma_{el}^{zz} \sim (\xi/R)^{1/2} \). Using these estimates one can calculate the relative magnitude of the terms in Eq. (10) and then compare their contribution to the rolling friction torque \( M \). After these calculations one arrives at

\[
M = -\Omega R \int \int dx dy \, y \partial_y \sigma_{el}^{zz}(E_1 \leftrightarrow \eta_1; E_2 \leftrightarrow \eta_2)
\]

(11)

where all other terms which are by a factor \( (\xi/R)^{1/2} \) smaller are omitted. Integrating by parts the right-hand side of Eq. (11) and taking into account that the stress tensor vanishes on the boundary of the contact circle one finally finds

\[
M = \Omega R \left\{ \int \int dx dy \, \sigma_{el}^{zz}(E_1 \leftrightarrow \eta_1; E_2 \leftrightarrow \eta_2) \right\}
\]

(12)

The expression in the curly brackets in Eq. (12) would coincide with the normal elastic force \( F_N^N \) (see Eq. (8)) if it would contain the elastic constants \( E_1 \) and \( E_2 \) instead of the dissipative constants \( \eta_1 \) and \( \eta_2 \). To perform the integration in Eq. (12) we apply the rescaling procedure proposed in [13]. The coordinates are transformed due to \( x = \alpha x', y = \alpha y' \) and \( z = z' \) with

\[
\alpha = \left( \frac{\eta_2 - \frac{2}{3} \eta_1}{\eta_2 + \frac{2}{3} \eta_1} \right) \left( \frac{E_2 + \frac{2}{3} E_1}{E_2 - \frac{2}{3} E_1} \right),
\]

(13)

so that the radius of the contact area in new coordinates is \( a = b = \alpha a' = \alpha b' \). One obtains

\[
\sigma_{el}^{zz}(E_1 \leftrightarrow \eta_1; E_2 \leftrightarrow \eta_2) = \beta \left( \eta_1 \frac{\partial u_{el}^z}{\partial z} + (\eta_2 - \frac{\eta_1}{3}) \left( \frac{\partial u_{el}^x}{\partial x} + \frac{\partial u_{el}^y}{\partial y} + \frac{\partial u_{el}^z}{\partial z} \right) \right)
\]
\[
\beta = \frac{1}{\alpha} \frac{m_2 - \frac{1}{2} \eta_1}{E_2 - \frac{1}{3} E_1}.
\]

As it follows from Eq. (14) after the appropriate rescaling the desired expression for the stress tensor with the “replaced” constants may be written in the same way as in [3]. Integration in Eq. (12) yields the final result for the torque of the rolling friction in the quasi-static regime

\[
M = k_{rol} \Omega RF_N. \quad (15)
\]

It may be shown that in the quasi-static regime the normal force \(F_N\) which acts on the sphere coincides with \(F_{el}^N\) of the static problem. Fig. 1 explains the appearance the friction torque in the rolling motion. The rolling friction coefficient finally reads

\[
k_{rol} = \frac{1}{3} \frac{(3 \eta_2 - \eta_1)^2}{3 (3 \eta_2 + 2 \eta_1)} \left[ \frac{(1 - \nu^2)(1 - 2 \nu)}{Y' \nu^2} \right]. \quad (16)
\]

The latter expression relates the rolling friction coefficient to the elastic and viscous constants of the rolling body material.

It is interesting to note that the rolling friction coefficient \(k_{rol}\) coincides with the material constant \(A\) in the dissipative force \(F_{dis}^N = \rho A \sqrt{\xi} \xi\), \(\rho = \frac{Y' \nu^2}{1 - \nu^2} \sqrt{R}\) for two colliding spheres (for derivation see [13]). Using this expression one can calculate the normal coefficient of restitution \(\epsilon\) for two spheres which collide with relative velocity \(v\) [13]. This coefficient which measures the energy loss upon collision reads \(1 - \epsilon = C_1 A \rho^{2/5} v^{1/5} + \cdots \) \((C_1 = 1.15344)\) [10]. Therefore, one can find the rolling friction coefficient from the restitution coefficient of the same material. To get an estimate of \(k_{rol}\) we take \(1 - \epsilon = 0.1\) for steel particles of mass \(m = 10^{-2} kg\), colliding with impact velocity \(v = 1 m/s\) to obtain \(\rho^{2/5} = 10^3 (kg^2/m^5s)^{1/5}\) and \(k_{rol} = 10^{-6}s\). Up to our knowledge for the case of a soft sphere rolling on a hard plane the dependence of the rolling friction coefficient on the rolling body velocity has not been studied experimentally.

In conclusion, we found for the first time, to our knowledge, the first-principle expression which relates the rolling friction coefficient to the elastic and viscous properties of the material. Our calculations refer to the rolling motion of a viscoelastic sphere on a hard plane without slipping in the regime when the velocity of the sphere is much less then the speed of sound in the material and when the characteristic time of the process \(\xi/V\) is much larger than the dissipative relaxation times of the viscoelastic material.
