ABSTRACT Acceleration of global warming has emerged as one of the biggest environmental challenges facing poultry farming. In heat stressed flocks, massive mortality rates and substantial damage to productive performance (eggs and meat) are commonly noticed. Because birds do not have sweat glands, they cannot tolerate high temperatures, especially when combined with high humidity. Under this harsh environmental condition, the birds reduce their feed consumption to decline metabolic energy rate. At an ambient temperature of more than 26°C, the bird increases panting and reduces metabolic rate to get rid of the body’s heat increment. There are many scenarios that can be followed to alleviate the adverse effects of heat stress. Management practices, nutritional modification, and/or feed additives are frequently used in poultry farms. However, introducing major genes such as naked neck (Na), frizzle (F), slow feathering (K), and dwarf (dw) could be adopted as a significant solution to improve productive performance in birds raised under high environmental temperatures. The birds carrying these mutations gain popularity owing to their ornamental appearance and highly productive performance at high temperatures. Moreover, utilizing dwarf gene in broiler breeders as a dam line improves adaptability, survivability, and hatchability in flocks kept in hot climates. At hatch, the sex-linked slow feathering mutation has been widely used for wing sexing in some egg-type breeds. The potential use of major genes as a breeding strategy to enhance heat tolerance in chickens has been extensively reviewed.

Key words: major gene, naked neck, frizzle, dwarf, slow feathering

INTRODUCTION Escalating global temperatures combined with global increases in the number of poultry and the intensification of agriculture has resulted in heat stress becoming an important challenge facing poultry production. Heavy breeds (meat-type) are found to be more sensitive to heat stress than lighter breeds (egg-type). Huge economic losses in egg production and shell quality resulting from heat stress have occurred in laying hens. Under this unusual condition, the bird resorts to increase panting, which leads to excess removal of CO₂ from the blood (alkalosis case). According to this physiological mechanism, the availability of blood bicarbonate ions becomes limited for eggshell mineralization. Fortunately, some mutations, such as naked neck, frizzle, slow feathering, and dwarf, confer thermoregulation in hot and humid regions by reducing feather mass or body weight (Gowe and Fairfull, 2008; Desta, 2021). Additionally, reduced feather coverage leaves more dietary protein available to produce more meat yield and egg production. It is strongly recommended to develop commercial strains bearing Na and/or F genes in developing countries suffering from high ambient temperatures (Duah et al., 2020). In a hot environment, the genotypes carrying Na and/or F genes could be called thermo-tolerant chickens (Fathi et al., 2013, 2014). It was observed that use of the naked neck, frizzle, and dwarf genes helps birds to be adapted to heat stress without compromising production performance (Patra et al., 2002; Lin et al., 2006; Islam and Nishibori, 2009; Rajkumar et al., 2010). There are several native chicken breeds with ornamental appearance in Saudi Arabia. Native naked neck chickens are medium-sized with multicolored feathers (mostly black), while frizzle chickens are dark brown with black
feathers on the abdomen and tail (Fathi et al., 2017). It is strongly recommended to develop and commercialize naked neck and frizzled birds, especially in developing countries (Duah et al., 2020). Under a harsh tropical environment, incorporating dwarf gene into the broiler industry is strongly recommended (Horst, 1988; Dunnington and Siegel, 1998; Islam, 2005). The dwarf birds exhibited several advantages and pleotropic effects under heat stress, such as better reproductive fitness, lower feed consumption, better feed efficiency, and high disease resistance compared to their normal-sized siblings. A sex-linked dwarf gene has been suggested for use in broiler breeding programs through the heavy dam line to increase fertility and hatchability while saving floor space (Isalm, 2005). In the present review, the influence of major genes on productive performance in chickens has been discussed and reviewed.

**FEATHER COVERAGE AND HEAT TOLERANCE**

In hot regions, a decline in feather coverage (surface and/or intensity) is of interest to increase productivity in poultry. Heat tolerance and, in turn, growth performance and reproductive traits in poultry can be improved through exploiting some valuable heat tolerant genes such as naked neck (Na), frizzle (F), and slow feathering (K) (Mérat, 1990; Lin et al., 2006; Gowe and Fairfull, 2008; Fathi et al., 2013). These genes have pleotropic effects beyond their impact on feathering rate.

The naked neck gene (Na) is an autosomal incompletely dominant gene located on the third chromosome. It reduces the feather coverage by about 40% in homozygous chickens and 20 to 30% in heterozygous siblings compared to their normal plumage counterparts (Mérat, 1990; Deeb and Cahaner, 1999; Lin et al., 2006; Fathi et al., 2013). The heterozygote state (Nana) shows an isolated feather throat tuft on the neck above the crop (Photo 1), while in the homozygous one (NaNa), the throat tuft is completely absent or reduced to a few units (Photo 2), and this baring extends to the abdomen and ventral side of femurs (Mérat, 1986; Somes, 1990; Fathi et al., 2014). The Na gene could be considered as a marker gene because the feather appearance of different genotypes can be identified by visual examination upon hatching (Photo 3). Galal et al. (2019) found that the naked neck gene improved heat tolerance by increasing HSP70 gene expression rather than by reducing feather cover in Egyptian local breeds raised under heat stress conditions. Additionally, the Na gene increases the size of head appendages (wattle and comb), instigating more body surface to thermoregulation and loss of heat (Chen et al., 2002; El Syaid et al., 2011; Desta, 2021). Reduced feather surface development leaves extra protein for vital physiological functions and produces more eggs and meat. In addition, featherless area reduces the population of lice and mites that are preferentially concentrated under scavenging production systems (Tabler et al., 2017; Desta, 2021). In cold weather, the Na gene has less advantages of productive performance, which shows gene by environment interaction (Rajkumar et al., 2011). For extremely appearance, there is an autosomal recessive mutation (scaleless, sc/sc) that causes completely feather loss (featherless birds) and enhances thermotolerance, especially in fast growing broilers (Cahaner et al., 2008; Renaudeau et al., 2012). However,
scaleless chicken might be less preferred by some societies (Besbes et al., 2007; Desta et al., 2013; Desta, 2021). In addition to preference, scaleless birds are susceptible to parasites, sunburn, and cold weather, as well as show difficulties in copulating (Bartels, 2003). Consequently, chickens with naked neck are preferred over scaleless ones.

The frizzle gene (F), an incompletely dominant gene, reduces the intensity of feathers, making the birds dissipate the excess body heat more efficiently. Dong et al. (2018) demonstrated that a deletion allele in KRT75L4 is responsible for the frizzle feather phenotype in Kirin, a Chinese indigenous chicken, and not KRT6A, as in other breeds of frizzle chickens. Frizzling appearance can be identified in newly hatched chicks after 3 to 4 d (Galal and Fathi, 2002). The frizzle gene reduces the feather insulation through curling and reducing the intensity of feathers (Lin et al., 2006; Fathi et al., 2013). In the adult frizzled birds (FF and Ff), the feathers become curled and more delicate compared to the normal case (ff). The contour feathers become curled outward and upward, while rectrices and remiges are less affected but have an irregular appearance. Other structural abnormalities could be noticed in some cases, like thickening of the barbs and barbules, and alteration of the hooklets (Dong et al., 2018). This modification in feather structure reduces the insulating effect of feather coverage. The frizzled appearance is more obvious in a homozygous state (Photo 4) compared to heterozygous siblings (Photo 5). At the older age, the feathers break easily and the bird tends to be completely naked, especially in FF state (Mérat, 1990; Stevens, 1991; Fathi et al., 2013). From the heat tolerance point of view, the frizzle gene behaves as a recessive mutation (Zerjal et al., 2013). No significant difference was detected between heterozygous carriers (Ff) and normally (ff) feathered hens. The combination of Na and F genes gives low feather intensity and more heat dissipation, particularly when the Na exists in a homozygous state (NaNaF-). There is an additive effect in the double heterozygous (Na/Na F/f) broiler (Yunis and Cahaner, 1999). So, the frizzle gene is another potential target for developing heat-tolerant chickens. However, the beneficial effect of the F gene as compared to the Na gene is lower in broilers at high temperatures.

The slow feathering phenomenon is a wonderful sex-linked mutation used for sex identification of day-old chicks in some egg-type strains at hatch, providing an accurate and low-cost effective method. It is considered a multiple allelic trait, which has 4 different alleles (extremely slow, Ks, slow feathering, K, delayed feathering, k+, and rapid feathering, k+) switched on the same locus (McGibbon, 1977). The direct gene action concerns the growth of feathers’ wing in newly hatched chicks, especially remiges and rectrices. Slow feathering strains inherently have better thermoregulation due to less heat production (Mérat, 1986; Fayeye et al., 2006;
An improvement in heat dissipation and economic traits (feed intake, growth rate, fitness) may be expected due to this mutation (Fotsa et al., 2001). Slow feathering locus has pleotropic effects beyond its impact on feathering (Leeon and Walsh, 2004). Its effects on broiler metabolism, immune response, heat tolerance, susceptibility to ascites, fat deposition, and carcass yield are well documented (Critenden et al., 1987; Singh et al., 2001; Pakdel et al., 2002; Zerehdaran et al., 2004; Khosravinia, 2009). It could be noticed that the slow-feathering chicks are more capable of withstanding post-hatch broiler chicks transported for extended periods without access to feed compared to rapid feathering sibs (Khosravinia and Manaﬁ , 2016). A better adaptability of dwarf hens to heat was observed only in one experiment (Mutibvu et al., 2018). Birds having Na or F genes had signiﬁcantly improved body weight at the onset of laying compared with normally feathered counterparts (Abou-Emera et al., 2017). However, the positive effect of the F gene on the growth rate of broilers is less than the effect of the Na allele under high temperatures (Lin et al., 2006; Pawar et al., 2016). Furthermore, there is an additive effect in the heterozygous gene utilization (Na/Na F/f) in broiler chickens (Yunis and Cahaner, 1999). With respect to the rate of feathering, Khosravinia (2009) reported that a signiﬁcantly increased live weight and carcass yield compared to their normal plumage counterparts (Adomako et al., 2014a). Higher meat yield due to the presence of the Na gene is well established (El-Attar and Fathi, 1995; Yalcin et al., 1999; Fathi et al., 2008). Rajkumar et al. (2011) reported that the naked neck chickens showed a signiﬁcantly greater increase in live weight, dressing yield, thigh and giblet weight than their normal siblings. The increasing thoracic muscles associated with the Na allele might be due to less dietary protein requirement, leaving more protein for muscle development compared with full feather counterparts (Merat, 1990; El-Attar and Fathi, 1995; Reddy et al., 2015). Moreover, naked neck chickens exhibited less cannibalism behavior compared to normally feathered siblings, resulting from a lower protein requirement and a lower mass of feathers (Barua et al., 1998; Deeb and Cahaner, 1999; Gowe and Fairfull, 2008). In Ghana, the indigenous naked neck (Na/na) chickens are preferred over their normal plumage counterparts for meat yield and quality (taste, texture, and water holding capacity) (Duah et al., 2018). Due to a reduced feather cover, naked neck chickens need less time and cost for feather scalding and plucking leaving a carcass smoothly dressed (Moyle et al., 2011; Parker et al., 2014; Tabler et al., 2017). In the developing countries, the naked neck genotypes are preferred in flocks raised under scavenging and free-range systems. The naked neck chickens require less amount of drinking water, which enable them to be adapted for raising in dry lands (Chikumba and Chimonyo, 2014). The naked neck chickens spend more time on foraging compared to normally feathered ones indicating their enhanced adaptation (Mutibvu et al., 2018). Birds having Na or F genes had signiﬁcantly increased body weight at the onset of laying compared with normally feathered counterparts (Abou-Emera et al., 2017). However, the positive effect of the F gene on the growth rate of broilers is less than the effect of the Na allele under high temperatures (Lin et al., 2006; Pawar et al., 2016). Furthermore, there is an additive effect in the heterozygous gene utilization (Na/Na F/f) in broiler chickens (Yunis and Cahaner, 1999; Fisinin and Kavtarashvili, 2015). With respect to the rate of feathering, Khosravinia (2009) reported that a signiﬁcantly increased live weight and carcass traits were noticed in rapid feathering chickens compared to slow feathering ones of commercial broiler
flocks. In turkeys, differences in body weight and carcass characteristics were found between slow feathering males and fast feathering females (Sikur et al., 2004). On the other hand, the presence of sex-linked slow feathering gene in the chicks kept under hot environment (31°C) did not influence growth rate, feed intake, and feed efficiency (Fotsa et al., 2001). In broiler breeders, the sex-linked recessive gene for dwarfism (dw) reduced adult body size by 30 to 40% and lowered metabolic heat production (Lin et al., 2006; Pawar et al., 2016). The dw gene shortens shank length by about 25% in heavy weight breeds compared with 6% in light weight breeds (Photo 6) (Reddy and Siegel, 1977; Hussain et al., 1982). Accordingly, dwarf birds become more suitable for adaptation to hot climate by getting rid of the excess heat through radiation and convection (Horst and Petersen, 1977; Islam, 2005). The advantages of major genes for growth performance and carcass characteristics under hot temperatures are summarized in Table 1.

**EGG PRODUCTION AND EGG QUALITY**

It is well known that egg production and quality deteriorate under hot weather conditions. In general, many reports stated that the presence of Na or F gene significantly increased laying performance and eggshell quality, especially breaking strength in laying hens kept at high environmental temperatures (Mérat, 1990; Galal, 2000; Singh et al., 2001; Mahrous et al., 2008; Abou-Emera et al., 2017). Because of their enhanced heat dissipation, both frizzle genotypes (homozygous and heterozygous) have relatively higher meat and egg production than wild type individuals under tropical conditions (Mathur, 2003; Adomako et al., 2014b). The superiority of the homozygous state (FF) was evident for all egg quantity and quality traits. Besides, the presence of Na and F genes in laying hens raised under low ambient temperature significantly increased shell thickness and, in turn, improved shell strength (Fathi et al., 2019). The heterozygous naked neck (Nana) genotype significantly improved the Haugh unit and shell thickness compared to the normally feathered one. Additionally, the naked neck and frizzled genotypes attained sexual maturity earlier than normal plumage hens (Abou-Emera et al., 2017).

Islam (2005) found that the dwarf hens attained sexual maturity earlier than normal size sisters at hot environment (30°C). Besides, the existence of dw gene reduced vitellogenesis, resulting in a greater reduction of defective eggs, such as double yolked, shell less, soft shelled eggs and, in turn, higher normal hatching eggs (Anonymous, 2003; Islam, 2005). Nevertheless, slow-feathering chickens show a reduction in egg production and need a higher amount of dietary energy (Wilson et al., 2007). It was found that the slow feathering gene (K) adversely affected fertility, embryonic mortality, hatchability, and egg production traits, except for egg weight at 22°C rearing temperature (Goger et al., 2017). However, Mincheva et al. (2012) reported that the egg production traits of hybrids were not negatively affected by the slow feathering (K) gene.

In terms of ultrastructural properties of eggshell, Mahrous (2012) reported that Nanaff and NanaFf genotypes exhibited a good confluence of mammillary caps and early fusion among calcite columns compared to the nanaff genotype. In an intensive eggshell ultrastructural study, Radwan (2014) pointed to a positive effect on the increasing length of the palisade layer of eggs laid by hens carrying Na and/or F genes. Additionally, the presence of the Na gene in a single state or combined with the F gene significantly increased the total mammillary thickness compared to eggs from the nanaff genotype (Mahrous and Galal, 2011). It is well known that the palisade layer provides the stiffness of the eggshell, thus imparting strength to the egg (Bain, 1992). A weak attachment between caps and the inner shall membrane resulting from increased type B bodies was clearly observed in eggs produced from the normally feathered genotype compared with those produced from naked neck and frizzled siblings (Mahrous, 2012). Tables 2 and 3 show the effects of major genes on productive performance and eggshell quality, respectively.

**REPRODUCTION PERFORMANCE**

It is well recognized that fertility and hatchability represent significant factors affecting reproductive performance in poultry breeding programs. Major genes affecting fertility and hatchability of chickens kept under high environmental temperatures have been reported (Mérat, 1990; Renema et al., 2008; Ajayi and Agaviezor, 2016). In general, the hatchability

*Photo 6. Dwarf male (dwdw) shows short shank length (short-legged bird). All photos are taken from the chicken flock belonging to research station, College of Agriculture and Veterinary Medicine, Qassim University, SA.*
percentage in naked neck chickens was low due to the high incidence of late embryonic mortality (Mérat, 1986; Rajkumar et al., 2012). Embryonic mortality in the late developing stage is significantly increased, and the homozygous genotype (NaNa) is more affected than the heterozygous embryos (Nana). The possible reason for the Na gene-induced embryonic mortality is still not clear (Sharifi et al., 2010). However, Peters (2005) concluded that the Na gene is likely to be lethal when present in a dominant form. Nevertheless, better fertility and hatchability estimates were recorded in chickens carrying the Na gene at high and humid temperatures (Ladjali et al., 1995). Furthermore, Sharifi et al. (2010) reported that the normally feathered genotype (nana) showed an inferior performance in reproductive traits, viz. fertility, hatchability, and number of live chicks in comparison with the homozygous genotype (NaNa) under thermal stress. Among Nigerian local chickens, the frizzle gene is more desirable in improving fertility and hatchability traits, while the naked neck gene appears to have a lethal effect on embryonic development (Adeleke et al., 2012). Similarly, Peters et al. (2008) found that frizzled cockerels produced higher semen quality, including volume, motility, and concentration compared with their naked neck counterparts. In terms of slow feathering mutation, it was observed that fast feathering genotypes had higher hatching traits than those of slow feathering ones (Goger et al., 2017). Slow-feathered turkeys show inferior reproductive efficiency compared with their fast-feathered counterparts (Renema et al., 2008). Moreover, slow-feathered chickens show late sexual maturity (Wilson et al., 2007). Better reproductive fitness (fertility and hatchability) and more hatching eggs were observed in dwarf breeders

| Trait                  | Gene function | Ambient temperature | Reference                  |

compared to normal-sized siblings raised in the tropics (Islam, 2005).

**IMMUNITY AND HEALTH**

There is no doubt that some major genes are believed to increase the bird’s adaptability to defeat heat stress and improve disease resistance as well. Numerous reports concluded that Na and F genes could be used in selection programs of chicken breeds raised in hot climates to improve immunocompetence traits and decrease mortality rate. Lower mortality rate and higher disease resistance were reported for naked neck birds over normally feathered siblings (Mahrous et al., 2008; Islam and Nishibori, 2009; Fathi et al., 2019). In the tropics, higher disease resistance and lower mortality rate were associated with birds carrying Na, F, and dw genes compared to those having normal plumage (Njenga et al., 2005). The naked neck gene significantly increased cell-mediated responses. Homozygous naked neck (NaNa) chickens had a higher response to phytohemagglutinin-P (PHA-P) challenges compared with both heterozygous (Nana) and normally feathered siblings raised in the tropics (Islam, 2005).

### Table 2. Effect of major genes on egg production performance and egg quality.

| Trait                          | Gene function | Ambient temperature | Reference                        |

(nana) genotypes at high ambient temperatures (Nazmi, 2006; Galal, 2008). Additionally, El-Safty, 2006 noticed that the heterozygous genotype of the naked neck gene had a significantly greater dermal swelling response to PHA-P compared to the normally feathered one in laying hens kept under winter conditions. At low ambient temperatures, the presence of Na and F genes greatly enhanced cellular immunity, particularly in heterozygous naked neck status (Fathi et al., 2019). In the laying hen population, Fathi et al. (2005) and Abou-Emera et al. (2017) demonstrated that the presence of Na and F genes significantly increased cell mediated response at all interval times as compared to normally feathered genotype. Similarly, Patra et al. (2004) confirmed that both the NaNa and Nana genotypes have better cellular mediated immunity when compared to the nana sibs. On the other hand, Martin et al. (1989) and Haunshi (1999) did not find a positive effect of Na and F genes on cell-mediated response to concanavalin A.

In terms of humoral immunity, the Na gene significantly increased antibody titers against to SRBC (Fathi et al., 2005; Galal and Mahrous, 2011; Rajkumar et al., 2011). Nevertheless, Haunshi et al. (2002) reported that there were no significant differences in antibody response to SRBC in heterozygous naked neck and frizzled birds when compared with their normally feathered counterparts. Several studies have revealed that the Na gene has more resistance against bacterial, viral, and parasitic infections. Naked neck birds have a higher carbon clearance index, that is, higher phagocytosis compared to normal birds (Fathi et al., 2005; Nazmi, 2006; Mahrous, 2008; El Syaid et al., 2011). Conversely, Haunshi et al. (2002) reported that there was no difference between naked neck and normally feathered genotypes for the ability of phagocytosis. Naked neck chickens did not show signs of sudden death or ascites syndrome (Gonzales et al., 1998, 1999).

Dwarf laying hens have better resistance to Marek’s disease, showing lower mortality in birds injected with Marek’s disease under heat stress (Dunnington and Siegel, 1998). In addition, Islam (2005) stated that sex-linked dwarf (dw) birds may have more competent T-cell subpopulations and weaker B-cell reactivity compared to normal ones. Dwarf chickens had consistently higher or equivalent cell-mediated immunity responses compared to their normal counterparts (Klingensmith et al., 1983). On the other hand, no adverse effect was found due to introducing dwarf and slow feathering genes on the immunocompetence of chickens (Klingensmith et al., 1983; Bacon et al., 1986). Records of immune response and lymphoid organs according to several authors are summarized in Table 4.

**BLOOD HEMATOLOGY AND BIOCHEMISTRY**

In naked neck chickens raised under high ambient temperatures, the increased growth rate may be associated with a high concentration of triiodothyronine hormone (Decuypere et al., 1993; Lin et al., 2006). It also reduces fat deposition in skin and breast muscles, which increases heat dissipation via the neck and bare surface (Raju et al., 2004). The existence of the Na gene reduces triglycerides and cholesterol content (very low and low-density lipoprotein), while it increases high-density lipoprotein (Patra et al., 2002; Rajkumar et al., 2010;
Mahrous and El-Dlebshaney, 2011). Accordingly, blood cholesterol and the accumulation of fat could be reduced (Rajkumar et al., 2010). In addition, Duah et al. (2020) demonstrated that the nanaff genotype birds had significantly higher cholesterol levels than in both the Nanaff and NanaFF genotype states. In terms of health, the indigenous naked neck genotype appears to be superior due to its low fat and cholesterol content. On the other hand, there were insignificant differences in the concentrations of cholesterol, triglycerides, and thyroid hormones among naked, frizzle and normally feathered genotypes (Peters et al., 2011; Fathi et al., 2019). At low ambient temperatures, the Na and F genes increased hemoglobin concentration, white blood cells, and oxygen demand compared to the normal plumage genotype (Monnet et al., 1979; Yahav et al., 1998; Peters et al., 2011). A higher haematocrit value in birds carrying the genotype (Yahav et al., 1998; Galal, 2008; El-Safy, 2006). The Heterophil (H)/Lymphocyte (L) ratio has been considered as the indicator of stress condition in chickens. Rajkumar et al. (2011) demonstrated that the naked neck chickens had a significantly lower H/L ratio than their normal siblings, indicating less heat stress under high temperatures. An increased H/L ratio was found in the normal plumage genotype compared to the naked neck one under low ambient temperature (El-Safy, 2006). According to the findings of Mahrous et al. (2008), introducing the Na or F gene, either alone or in combination, significantly increased plasma total protein and globulin levels compared to the normal plumage state (nanaff). When compared to frizzled and naked neck genotypes, the normally feathered birds had higher serum glucose, urea, and creatinine levels (Peters et al., 2011). Under summer conditions, the lipid peroxidation concentration was higher in normally feathered birds compared to naked neck sibs, resulting in higher concentration of malondialdehyde (MDA) in the blood (Rajkumar et al., 2011).

In dwarf laying hens, the naked neck gene (single or double segregation) had a significantly lower cholesterol level as compared to normal sized siblings (Galal et al., 2007). In terms of liver function, the inclusion of dw, Na, and their combination greatly enhanced liver function by reducing liver enzymes (GOT and GPT) as compared to Dw-nana counterparts. Moreover, the inclusion of dw gene in a single manner or in combination with the Na gene significantly reduced plasma T3 compared to normal (Dw-nana) birds (Galal et al., 2007). Blood parameters as affected by major genes are listed in Table 5.

### THE INTERACTION AMONG MAJOR GENES

It seems that the heat tolerance was improved in the double heterozygous chickens (NaNaFf) compared with the single state genotypes (Yunis and Cahaner, 1999; Mahrous, 2008). In terms of productive performance, several studies have reported that the combination of Na and F genes appeared to have a positive interaction on body weight, feed conversion, egg production, disease resistance, and immune response, particularly at high ambient temperatures (Mahrous and El-Dlebshaney, 2011; Fathi et al., 2013, 2014). When compared to the normal genotype, introducing the Na gene alone or in combination with an F gene significantly improved egg quality and/or shell quality (thickness and breaking strength; Zulkifli et al., 1992; Mahrous and El-Dlebshaney, 2011). Moreover, a favorable effect on ultrastructural properties was noticed in eggs laid by laying hens carrying a combination of Na and F genes (Mahrous and Galal, 2011; Radwan, 2014). In addition, Missohou et al.
| Mutation       | Symbol | Dominance          | Direct gene action/description                                                                 | Pleotropic effects                                                                 |
|---------------|--------|--------------------|------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------|
| Naked neck (Na) | Na > na | Incompletely dominant autosomal gene | Reduces the feather coverage by about 40% in homozygous and 20-30% in heterozygous chickens. The neck becomes completely bare in homozygous with feather tuft in heterozygous state. | • Heat shock proteins is rapidly synthesized.  
• Enhances immunocompetence.  
• Improves eggshell quality.  
• Increases breast meat.  
• Increases body weight and egg production. |
| Frizzle (F)    | F > f  | Incompletely dominant autosomal gene | Feathers become curling outward and more delicate. Reduces feather intensity.                  | • Enhanced heat dissipation.  
• Increases meat yield and egg production.  
• Enhances immunocompetence. |
| Dwarfism (dw)  | Dw > dw | Recessive sex-linked gene | Reduces body weight by about 30-40% in females and homozygous males.  
Shortens shank length by about 25% in heavy weight breeds. | • Improves feed conversion rate.  
• Reduces metabolic heat output  
• Decreases defective eggs and increases settable eggs.  
• Better resistance to diseases.  
• Enhances immunocompetence. |

(2003) found that the interaction between the dwarf and frizzle genes was only positive for growth traits and egg number in Senegal’s tropical climate. On the other hand, there was no gene-by-gene interaction when frizzle-dwarfed birds (FFdw-) were kept at a moderate ambient temperature (24°C). The genotype combining the 2 major genes (FFdw-) proved to be inferior to the normally feathered dwarf genotype (ffdw-) for laying traits but superior in fertility (Sharifi et al., 2010).

CONCLUSIONS

Heat stress is considered the biggest concern affecting productive performance in the poultry industry. It has been established that the Na and F genes (alone or in combined status) are highly tolerant to high environmental conditions and can improve both growth performance and egg production. Implanting a sex-linked dwarf gene in broiler breeder maternal lines improves the profitability of the project under hot climate. Lower requirements for housing and feed, better survivability and fertility, improved hatchability, increased feed efficiency, and resilient resistance to disease could be achieved. Using sex-linked slow feathering mutation for auto-sexing in chicks of some egg-type strains at hatch provides an accurate and low-cost effective method. Table 6 summarizes and describes the morphological appearance, direct action, and pleotropic associated effects of the major genes under hot environmental conditions. Additionally, a schematic diagram illustrating the improvement or deterioration that occurred in the productive traits of genotypes carrying major genes is given (Figure 1).

DISCLOSURES
