Surface- and subsurface-dwelling planktonic foraminifera from the upper 43 m of Hole A at the Ocean Drilling Program (ODP) Site 807, which was recovered from the western Pacific warm pool during ODP Leg 130, were analyzed for stable oxygen and carbon isotopes. By comparing these results with data from ODP Site 851 in the eastern equatorial Pacific, this study has reconstructed the paleoceanographic changes in upper ocean waters in the equatorial Pacific since 2.5 Ma. During the period from 1.6–1.4 Ma, the oxygen isotopes of surface and subsurface waters were found to markedly change in the western and eastern equatorial Pacific, further confirming the final formation of the well-defined asymmetric east-west (E-W) pattern at that time. This feature was similar to the zonal temperature gradient (sea surface temperature is higher in the west and lower in the east) and the asymmetric upper water structure (thermocline depth is deeper in the west and shallower in the east) in the modern equatorial Pacific. The zonal gradient change of subsurface water δ18O was greater than that of surface water δ18O, indicating that the formation of the asymmetric E-W pattern in the equatorial Pacific should be much more related to the shoaled thermocline and markedly decreased subsurface water temperature in the eastern equatorial Pacific. Moreover, since ~1.6 Ma, the carbon isotopic differences between surface and subsurface waters clearly decreased in the equatorial Pacific, and their long-term eccentricity periods changed from 400 ka to ~500 ka, reflecting the reorganization of the ocean carbon reservoir. This probably resulted from the deep water reorganization in the Southern Ocean at that time and its enhanced influence on the tropical Pacific (especially subsurface water). Our study demonstrates that the tropical ocean plays an important role in global climate change.

equatorial Pacific, oxygen and carbon isotopes, east-west asymmetric pattern, subsurface water, early Pleistocene

Along with the increasing attention to El Niño/Southern Oscillation (ENSO) and monsoonal climate in recent years, it has been widely accepted that the low-latitude tropical ocean plays a key role in global climate systems. This is particularly so in the equatorial Pacific Ocean due to the western Pacific warm pool (WPWP) [1] in the west and the “cold tongue” in the east. In the modern equatorial Pacific, there is a long-term and relatively stable east-west (E-W) asymmetric pattern of the zonal temperature gradient (sea surface temperature is higher in the west and lower in the east) and the asymmetric upper water structure (thermocline depth is deeper in the west and shallower in the east). Once the asymmetric pattern changed, the tropical climate signals would be transmitted through the exchange of water vapor and heat to the sea in middle and high latitudes and hence influence global climate change [2,3]. Therefore, the time and cause of this asymmetric pattern in the zonal temperature and thermocline gradients for the western and eastern equatorial Pacific has naturally become a topical and relevant research topic for paleoceanographic and paleoclimatic studies of the tropical Pacific. Recently, Wara et al. [4–6] found that the E-W zonal temperature gradient across the tropical Pacific was formed finally at ~1.6 Ma, based on the sea surface temperature (SST) reconstruction by the Mg/Ca ratios of surface-dwelling planktonic foraminifera.
research has revealed that at ~1.6 Ma, in the early Pleistocene, the chemical divide between well-ventilated intermediate water and poorly ventilated deep water was intensified in the Southern Ocean [7]. This reorganization of ocean circulation at high latitudes possibly not only affected the upper water structure and resulted in the E-W asymmetry in the tropical Pacific [8], but also caused a change in the ocean carbon reservoir, such as obscuring the 400 ka cycles in $\delta^{13}C$ since 1.6 Ma at Ocean Drilling Program (ODP) Site 1143 in the southern South China Sea [9]. However, previous studies of the early Pleistocene E-W asymmetry of the tropical Pacific mainly focused on the SST [4–8], ignoring the changes of subsurface water. In fact, modern oceanographic studies have demonstrated that the abnormal subsurface temperature in the tropical Pacific has a closer relationship to ENSO events [10,11]. There is some evidence that during the late Quaternary glacial cycles, the change in tropical subsurface water was even more significant than that of surface water [12,13], showing the particular importance of tropical subsurface water in climate change.

Therefore, this study selected the upper 43 m of Hole A at ODP Site 807 in the central WPWP for the stable oxygen and carbon isotopic analyses of surface- and subsurface-dwelling planktonic foraminifera. On the basis of the comparison with the records from ODP Site 851 from the eastern equatorial Pacific [14], the paleoceanographic changes of upper ocean waters in the equatorial Pacific since 2.5 Ma were reconstructed for exploring the response of subsurface water changes to the formation of the E-W asymmetric pattern in the tropical Pacific, and hence providing new scientific evidence to better understand the role of the tropical Pacific in global climate change.

1 Material and methods

The materials used in this study are from the upper 43 mbsf (meters below sea floor) of Hole A (822.9 m long) at ODP Site 807 (3°36.42′N and 156°37.49′E, water depth 2804 m, Figure 1), which was recovered from the Ontong-Java Plateau in the western equatorial Pacific during ODP Leg 130. The sediments are well preserved and relatively homogeneous in lithology, mainly consisting of light gray-white silty foraminiferal ooze with weak biological disturbance. According to the ODP scientific report for this site [15], the bottom age of the upper 43 m at Site 807A is ~2.5 Ma, in the early Quaternary. A total of 860 samples were analyzed in this study, with a sampling interval of 5–10 cm. Oxygen and carbon stable isotope measurements were carried out on surface-dwelling planktonic foraminiferal species Globigerinoides ruber (white, 300–360 μm) and subsurface-dwelling species Pseudovolvaria obtenuculata (360–440 μm). Analytical precision referred to the Chinese national carbonate standard GBW04405 and international standard NBS19. The standard errors of $\delta^{18}O$ and $\delta^{13}C$ in 2005 were $0.08\%e$ and $0.06\%e$ (PDB, Pee Dee Belemnite), respectively. The $\delta^{18}O$ and $\delta^{13}C$ of G. ruber are marked as $\delta^{18}O_{G. ruber}$ and $\delta^{13}C_{G. ruber}$, whereas those of P. obtenuculata are marked as $\delta^{18}O_{P. obtenuculata}$ and $\delta^{13}C_{P. obtenuculata}$ respectively. All the stable oxygen and carbon isotopic measurements were performed at the State Key Laboratory of Marine Geology at Tongji University.

2 Chronological framework

Besides the shipboard bio- and magneto-stratigraphic age points for ODP Site 807A [15], two more planktonic foraminiferal biostratigraphic data, the last appearance datum (LAD) and first appearance datum (FAD) of pink G. ruber at 1.92 mbsf (120 ka) and 6.67 mbsf (400 ka), respectively, were considered in this study. The age model for Site 807A (Figure 2) was built on the basis of the comparison of $\delta^{18}O_{G. ruber}$ with the LR04 stack benthic foraminiferal $\delta^{18}O$ curve [16]. Figure 2 shows that the upper 43 m part of Site 807A recorded the sedimentary history of the last ~2.5 Ma, including MISs 1-99, with an average sampling time resolution of ~3 ka.

3 Zonal $\delta^{18}O$ gradient in equatorial Pacific surface and subsurface waters

Planktonic foraminiferal $\delta^{18}O$ measurements at ODP Site 807 in the western equatorial Pacific are shown in Figure 3(a). The surface water $\delta^{18}O_{G. ruber}$ varied between ~0.68‰e and ~2.50‰e with an average of ~1.52‰e, whereas the subsurface water $\delta^{18}O_{P. obtenuculata}$ varied between 0.15‰e and ~1.85‰e with an average of ~0.96‰e. According to a modern investigation of planktonic foraminiferal ecology [17], the surface-dwelling species G. ruber lives in the upper 50 m water, while the subsurface-dwelling species P. obtenuculata is found at a depth range of 100–150 m, in the upper part of thermocline [18]. In this study, the $\delta^{18}O_{P. obtenuculata}$ is 0.56‰e heavier than the $\delta^{18}O_{G. ruber}$ on average. If $\delta^{18}O$ gains 0.26‰e in accordance with a water temperature decrease of 1°C [19], the subsurface water temperature represented by

Figure 1 Location of ODP Site 807. The 28°C isotherm marks the boundary of the western Pacific warm pool. ODP Site 851 in the eastern Pacific is also shown in this map.
of 0.6–1.2 Ma, the amplitude of temperature represented by the marine isotopic stage (MIS).

**Figure 2** Age model for ODP Site 807. (a) Depth-δ¹⁸O curve at Site 807; (b) LR04 stack δ¹⁸O curve of global benthic foraminifera [16]; (c) age-δ¹⁸O curve at Site 807. Arrows in (a) indicate the depths of bio- and magnetostratigraphic data; numbers above the δ¹⁸O curves in (b) and (c) mark the marine isotopic stage (MIS).

δ¹⁸O$_{P. obliquiloculata}$ was ~2°C lower than the surface water temperature represented by δ¹⁸O$_{G. ruber}$. Based on observational data from the modern ocean (WOA 05 [20]), the water temperature at a depth of 50 m on the Ontong-Java Plateau in the western Pacific is 28.5–29.0°C and at a depth of 100 m is 26.5–27.0°C. The temperature difference between them is 2°C, illustrating that the oxygen isotope results agree with the actual data. Therefore, the stable isotopes of *G. ruber* and *P. obliquiloculata* could be used to represent the isotopic variations in surface and subsurface waters, respectively, in the western Pacific.

Since 2.5 Ma (early Quaternary), the surface and subsurface δ¹⁸O changes at Site 807 in the western equatorial Pacific were generally consistent: prior to the “mid-Pleistocene transition” [21] of 0.6–1.2 Ma, the amplitude of δ¹⁸O fluctuations was relatively small with the dominant 41 ka obliquity cycle; after that, it obviously increased with the dominant 100 ka eccentricity cycle; in between, there was the transitional period for the δ¹⁸O change. However, recent research has revealed that the “mid-Pleistocene transition” could start from ~1.5 Ma [22], corresponding to the final formation of the zonal SST asymmetric pattern in the equatorial Pacific during the same period [4]. We calculated the δ¹⁸O differences between subsurface and surface waters (Δδ¹⁸O$_{P. obliquiloculata-G. ruber}$) at Site 807 and found an increasing trend after 1.4 Ma (Figure 3(b)), which was different from the situation at ODP Site 851 (2° 46′ N, 110° 34′ W, in a water depth of 3760 m) in the eastern equatorial Pacific (at this site, the δ¹⁸O differences between subsurface and surface waters Δδ¹⁸O$_{G. tumida-G. sacculifer}$ were calculated from the δ¹⁸O of subsurface-dwelling planktonic foraminiferal species *Globorotalia tumida* and surface-dwelling species *Globigerinoides sacculifer* [14]) (Figure 3(d)). In the western Pacific, the δ¹⁸O differences between subsurface and surface waters were usually used to indicate the variation of thermocline depth in the upper water column [23,24]. When the surface mixing increases and the thermocline depth becomes deep, the δ¹⁸O differences decrease, and vice versa. However, in the eastern equatorial Pacific upwelling region, when the upwelling increases, the thermocline depth will become shallower, resulting in a decreased vertical temperature gradient and hence decreased δ¹⁸O differences between subsurface and surface waters [14], opposite to that in the western Pacific. Therefore, since ~1.4 Ma, the thermocline depths in both the western and eastern equatorial Pacific have generally experienced a shoaling trend, although they displayed different amplitudes of change; in the eastern Pacific, the most remarkable change for the thermocline shoaling occurred during the period of 1.7–1.4 Ma (Figure 3(d)).

In the equatorial Pacific, estimates of both SST and δ¹⁸O show that the SST of the WPWP rose slightly after 1.6–1.4 Ma, while the “cold tongue” of the eastern Pacific steadily cooled, showing the end of the long-term El Niño-like conditions that had been present since 5 Ma (the Pliocene) and the final formation of the E-W asymmetric pattern in the equatorial Pacific. This can be proved from the surface water δ¹⁸O difference (Δδ¹⁸O$_{G. tumida-P. obliquiloculata}$) between the eastern and western equatorial Pacific. As shown in Figure 4, the subsurface water δ¹⁸O differences (Δδ¹⁸O$_{G. tumida-P. obliquiloculata}$) between the eastern and western equatorial Pacific were obviously greater than the surface water δ¹⁸O differences (Δδ¹⁸O$_{G. tumida-P. obliquiloculata}$) during the last 2.5 Ma, indicating that the asymmetric temperature phenomenon had existed for a long time across the equatorial Pacific, as mainly reflected in the subsurface water. After 1.4 Ma, both the Δδ¹⁸O$_{G. tumida-P. obliquiloculata}$ and Δδ¹⁸O$_{G. tumida-G. ruber}$ displayed a continuously increasing trend, reflecting the final formation of the long-term and relatively stable asymmetric pattern of the E-W temperature gradient in the equatorial Pacific. We selected 0.6 Ma (the typical 100 ka cycle started to be dominant after the middle Pleistocene climate transition) and 1.4–1.6 Ma (the final formation period of the E-W asymmetric pattern in the equatorial Pacific) as appropriate time boundaries to calculate average values for the periods 0–0.6 Ma, 0.6–1.4 Ma and 1.6–2.5 Ma, and found the subsurface water δ¹⁸O difference between ODP 851 and ODP 807 (Δδ¹⁸O$_{G. tumida-P. obliquiloculata}$) (1.75‰, 1.69‰ and
Figure 3 $\delta^{18}O$ variations in the western equatorial Pacific since 2.5 Ma. (a) $\delta^{18}O$ curves at ODP Site 807 in the western equatorial Pacific; (b) $\delta^{18}O$ differences $\Delta\delta^{18}O_{P.\,obliquiloculata-G.\,ruber}$ between subsurface water ($\delta^{18}O_{P.\,obliquiloculata}$) and surface water ($\delta^{18}O_{G.\,ruber}$) at ODP Site 807; (c) $\delta^{18}O$ curves at ODP Site 851 in the eastern equatorial Pacific; (d) $\delta^{18}O$ differences $\Delta\delta^{18}O_{G.\,tumida-G.\,saccularis}$ between subsurface water ($\delta^{18}O_{G.\,tumida}$) and surface water ($\delta^{18}O_{G.\,saccularis}$) at ODP Site 851. All the $\delta^{18}O$ data were 5-point smoothed at Site 807. Gray bar indicates the period from 1.4–1.6 Ma. Arrows show the general trend of $\delta^{18}O$ difference between subsurface and surface waters after 1.4 Ma in the western and eastern equatorial Pacific.

Figure 4 Zonal gradients of surface and subsurface water $\delta^{18}O$ between ODP Sites 851 and 807 across the equatorial Pacific. All the $\delta^{18}O$ data were 5-point smoothed. Gray bar indicates the period 1.4–1.6 Ma. Horizontal dashed lines mark the average $\Delta\delta^{18}O$ values in different time periods. Arrow shows the abrupt change of subsurface $\Delta\delta^{18}O_{G.\,tumida-P.\,obliquiloculata}$ around 1.4 Ma.

$1.40\%e$, respectively) were greater than the surface water $\delta^{18}O$ difference $\Delta\delta^{18}O_{G.\,saccularis-G.\,ruber}$ at the same time (0.85%e, 0.56%e and 0.34%e, respectively). Particularly at ~1.4 Ma, the subsurface $\Delta\delta^{18}O_{G.\,tumida-P.\,obliquiloculata}$ abruptly increased by 1.0%e (corresponding to ~4°C temperature increase in the E-W subsurface temperature gradient in the
equatorial Pacific), obviously greater than that of the surface $\Delta \delta^{18}O_{G. sacculifer-G. ruber}$ ($\sim$0.5‰; Figure 4). This implied that the E-W asymmetric pattern of subsurface water temperature in the equatorial Pacific was also established at 1.6–1.4 Ma (the early Pleistocene) and its change in amplitude was even more significant than that of the surface water.

4 Discussion of the causes of E-W asymmetric pattern formation in the equatorial Pacific

Because the sampling resolution for the period from 1.8–1.4 Ma at ODP Site 851 in the eastern equatorial Pacific was relatively low (Figure 3(c)), this study combines the results of previous studies [4–6] and takes the early Pleistocene (1.6–1.4 Ma) as the final formation period for the asymmetric E-W pattern in the equatorial Pacific. This was reflected in abruptly increased E-W temperature gradients in both the surface and subsurface waters, and even more so with significant changes in the subsurface water. During the period from 1.6–1.4 Ma, the upwelling strengthened in the eastern equatorial Pacific, which resulted in a shoaled thermocline and markedly decreased subsurface water temperature (around $\sim$1.4 Ma, the subsurface $\delta^{18}O_{P. obliquiloculata}$ in the western Pacific did not change much but the subsurface $\delta^{18}O_{G. tumida}$ in the eastern Pacific became remarkably heavier (Figure 3(a) and (c)). This led to the asymmetric E-W pattern of upper water structure in the equatorial Pacific, with a deep thermocline in the west and shallow one in the east. It is inferred that the asymmetric pattern of the zonal temperature gradient in the equatorial Pacific first occurred in the subsurface water and then led gradually to the formation of the asymmetric pattern in the SST [25] (Figure 4).

Modern ocean observation and numerical modeling research has revealed that the subsurface water in the western equatorial Pacific mainly originates from the “mode water” of the high latitude Southern Ocean, which submerges, flows northward to the low latitude, then to the eastern Pacific as the equatorial counter current where it induces upwelling [26,27]. Because the Southern Ocean is one of the two deep water upwelling zones in the world’s oceans, any change in deep water circulation in this area would affect the subsurface and surface waters of the equatorial Pacific and change the vertical structure in the upper water column [28]. Therefore, the formation of the E-W asymmetric temperature pattern in the equatorial Pacific during the period from 1.6–1.4 Ma coincided with the reorganization of ocean circulation in the Southern Ocean [7], and may have possible causal relationships between them [9].

According to the “leaking-Si” hypothesis [29,30], the Si-rich Antarctic mode water would submerge, flow northward and leak into the tropical subsurface water. This could then possibly induce a bloom of diatoms in the tropical ocean, changing the ocean carbon reservoir [9] and reducing the carbon dioxide content in the atmosphere. Actually, the early Pleistocene asymmetric pattern of the zonal temperature gradient across the equatorial Pacific can also be reflected in the carbon isotope records of planktonic foraminifera. As shown in Figure 5, the carbon isotopic differences between planktonic foraminiferal surface-dwelling species ($\delta^{13}C_{P. obliquiloculata}$ and $\delta^{13}C_{G. sacculifer}$) and subsurface-dwelling species ($\delta^{13}C_{P. obliquiloculata}$ and $\delta^{13}C_{G. tumida}$) in both the eastern and western equatorial Pacific obviously decreased after 1.6–1.4 Ma, implying that the carbon reservoir of upper water in the tropical Pacific significantly changed. Particularly, six carbon isotope maximum events, $\delta^{13}C_{max}$ to $\delta^{13}C_{max}$, since 2.5 Ma can be clearly recognized in Figure 5, with a ~400 ka cycle prior to 1.6 Ma and an average ~500 ka cycle after 1.6 Ma. This phenomenon is present in the global oceans including the southern South China Sea [9,31]. After 1.6 Ma, due to the effect of high latitude ice cover in the northern hemisphere, the regular ~400 ka “heart beating” cycle of the ocean carbon reservoir [32] was disturbed and the so-called “cardiac arrhythmia” phenomenon appeared. This probably indicated that the earth climate system was controlled by polar ice volume instead of solar radiation since that time [9].

Therefore, the final formation of the asymmetric E-W pattern of upper water structure in the equatorial Pacific during the early Pleistocene period (1.6 to 1.4 Ma) may be related to the reorganization of deep circulation in the Southern Ocean, and its main change could happen in the subsurface water. Once the E-W asymmetric pattern formed in the equatorial Pacific, the long-term permanent El Niño-like condition since 5 Ma (Pliocene) was closed in the equatorial Pacific [4–6]. The tropical climate signals would be transmitted through the exchange of water vapor to the sea in middle and high latitudes, affect the ocean carbon reservoir, and hence play an important role in global climate change.

5 Conclusions

(1) The oxygen isotopic difference $\Delta \delta^{18}O_P. obliquiloculata-G. ruber$ between planktonic foraminiferal subsurface-dwelling species ($P. obliquiloculata$) and surface-dwelling species ($G. ruber$) showed a generally increasing trend after 1.6–1.4 Ma at ODP Site 807 in the western equatorial Pacific. By comparison with paleoceanographic records from ODP Site 851 in the eastern equatorial Pacific, this study confirmed that the asymmetric E-W pattern of upper water structure, like the modern zonal temperature gradient, was finally formed during the period from 1.6–1.4 Ma in the equatorial Pacific. The change in the E-W gradient in the subsurface water $\delta^{18}O$ across the equatorial Pacific was greater than that in the surface water $\delta^{18}O$, indicating that the asymmetric pattern of the zonal temperature gradient across the equatorial
Pacific.first took place in the subsurface water and then gradually led to the formation of the asymmetric pattern in SST.

(2) Since 1.6–1.4 Ma (early Pleistocene), the planktonic foraminiferal carbon isotopic differences between subsurface- and surface-dwelling species markedly decreased in both the eastern and western equatorial Pacific, and their long-term eccentricity periods changed from 400 ka to ~500 ka, reflecting major changes in the ocean carbon reservoir. Therefore, the formation of the asymmetric E-W pattern in the equatorial Pacific during the period from 1.6–1.4 Ma coincided with the reorganization of ocean circulation in the Southern Ocean, and there may possibly be a causal relationship between them. This would change the ocean carbon reservoir and thus influence changes in global climate.

We thank two anonymous reviewers for constructive reviews, as well as the shipboard scientists of Ocean Drilling Program (ODP) Leg 130 for providing the samples used in this study.
