Compound Sequential Change-point Detection in Parallel Data Streams

Yunxiao Chen, London School of Economics and Political Science
Xiaoou Li, University of Minnesota

Abstract: We consider sequential change-point detection in parallel data streams, where each stream has its own change point. Once a change is detected in a data stream, this stream is deactivated permanently. The goal is to maximize the normal operation of the pre-change streams, while controlling the proportion of post-change streams among the active streams at all time points. Taking a Bayesian formulation, we develop a compound decision framework for this problem. A procedure is proposed that is uniformly optimal among all sequential procedures which control the expected proportion of post-change streams at all time points. We also investigate the asymptotic behavior of the proposed method when the number of data streams grows large. Numerical examples are provided to illustrate the use and performance of the proposed method.

Key words and phrases: Sequential analysis; Change-point detection; Compound decision; False non-discovery rate; Large-scale inference
1. Introduction

Sequential change-point detection, which dates back to the pioneering work of Page (1954, 1955), aims at the early detection of distributional changes in sequentially observed data. Methods for sequential change-point detection have received wide applications in various fields, including engineering, education, medical diagnostics, finance, among others, where a change point typically corresponds to a deviation of a data stream from its ‘normal’ state. The classical methods for sequential change-point detection focus on the detection of one or multiple changes in a single data stream (Lorden, 1971; Page, 1954; Roberts, 1966; Shewhart, 1931; Shiryaev, 1963). With the advances in information technology, large-scale streaming data become more common and many recent developments tend to focus on change-point detection in multiple data streams (Chan, 2017; Chen and Zhang, 2015; Chen, 2019; Mei, 2010; Xie and Siegmund, 2013; Fellouris and Sokolov, 2016).

In this paper, we consider sequential change-point detection in multiple parallel data streams, where each stream has its own change point. Once a change is detected in a data stream, this stream is deactivated permanently and its data are no longer collected. The goal is to maximize the normal operation of the pre-change streams, while controlling the proportion of
post-change streams among the active ones at all time points. This problem is commonly encountered in the real world. One such example is the monitoring of item pool in standardized educational testing (Choe et al., 2018; Cizek and Wollack, 2016; van der Linden and Lewis, 2015; Veerkamp and Glas, 2000). In this application, each item corresponds to a data stream, for which data are collected sequentially from its use in test administrations over time. A change point occurs when the item is leaked to future test takers. The goal is to detect and remove changed items in an item pool that consists of hundreds or even thousands of items in a sequential fashion. Once a change point is detected for an item, test administrators would like to remove it from the item pool to ensure test fairness. On the other hand, it is important to maximize the usage of each item before its leakage, due to the cost of developing new items. There are many other applications, including multichannel spectrum sensing (Chen, Zhang and Poor, 2020) and credit card fraud detection (Dal Pozzolo et al., 2017).

Despite its wide applications, this type of problems is rarely explored in the literature of multi-stream sequential change-point detection. One exception is Chen, Zhang and Poor (2020), who address a similar problem by proposing a sequential version of the Benjamini-Hochberg FDR control procedure (Benjamini and Hochberg, 1995) for detecting and deactivating
post-change data streams. However, no optimality theory is provided in Chen, Zhang and Poor (2020). The challenges of developing optimality theory lie in the compound nature of the FDR-type risk measure and the stochastic control component due to the deactivation of data streams. In this paper, we formulate the problem under a compound decision theory framework and propose an optimal change-point detection procedure. Our contributions are summarized below.

First, we formulate this problem under a Bayesian sequential change-point detection setting, which generalizes the classical Bayesian setting for single-stream change-point detection (Lai, 2001) to parallel streams. Moreover, we introduce new performance metrics, borrowing ideas from the compound decision theory for multiple hypothesis testing (Benjamini and Hochberg, 1995; Brown and Greenshtein, 2009; Cai et al., 2019; Efron and Hastie, 2016; Efron, 2019; Genovese and Wasserman, 2002; Sun and Cai, 2007; Zhang, 2003). Specifically, we propose to control a local False Non-discovery Rate (FNR) at each time point, defined as the expected proportion of post-change streams among the active ones under the current posterior measure. This metric adapts the FNR for multiple hypothesis testing (Genovese and Wasserman, 2002) to parallel-stream change-point detection. In addition, we introduce a compound stream utilization measure
that is closely related to the classical notion of average run length (Lorden, 1971). A compound sequential detection procedure involves a trade-off between local FNR and stream utilization at each time point and our objective is to maximize stream utilization, while controlling the local FNR to be below a pre-specified threshold all the time. Comparing with classical performance metrics for individual streams, the proposed metrics better evaluate the risk of sequential decision at an aggregate level and thus is more suitable for large-scale streaming data.

Second, we propose a sequential decision procedure that can control local FNR under any pre-specified threshold. Under a class of Bayesian change-point models, it is shown that this procedure is uniformly optimal among all the sequential detection procedures under the same local FNR constraint, in the sense that the proposed procedure has the highest stream utilization at any time. We emphasize that this is a non-asymptotic result that applies to any finite number of data streams. This result implies that this compound change-point detection problem is very special, in the sense that a myopic decision rule that maximizes the next-step stream utilization under the local FNR constraint is also uniformly optimal throughout time. Phenomenon of this kind does not hold in general for stochastic control problems (Howard, 1960). The proof of this uniform optimality result is
non-trivial, for which new mathematical tools are developed, including the
construction of monotone coupling over a partially ordered space (Thorisson
2000) for comparing stochastic processes with different dimensions due to
the deactivation step. Besides non-asymptotic optimality, asymptotic theory
is also established to characterize the performance of the proposed method
when the number of data streams grows large.

We point out that the current setting is substantially different from most
of the existing works on multi-stream sequential change-point detection,
including Mei (2010), Xie and Siegmund (2013), Chen and Zhang (2015),
Chan (2017), Chen (2019), and Chen, Wang and Samworth (2020). These
works consider the detection of a single change point, after which all (or part)
of the data streams deviate from their initial states. On the other hand,
the current work detects multiple change points in parallel streams. As the
dimension of the action space at each time point grows exponentially with
the number of data streams, the current problem tends to be computationally
and theoretically more challenging.
2. Compound Sequential Change-point Detection

2.1 Bayesian Change-point Model for Parallel Streams

Consider in total $K$ parallel data streams. For each $k = 1, ..., K$, the observations from the $k$th stream are $X_{k,t}$, $t = 1, 2, ...$. Each stream $k$ is associated with a change point, denoted by $\tau_k$, which takes value in $\{0\} \cup \{\infty\} \cup \mathbb{Z}_+$. The random vector $(\tau_1, \ldots, \tau_K)$ is assumed to follow a known prior distribution. Given the change points, the data points $X_{k,t}$ from the $k$th stream at time $t$ are independent for different $t$ and $k$. It is further assumed that the pre- and post-change distributions of $X_{k,t}$ have the density functions $p_{k,t}(\cdot)$ and $q_{k,t}(\cdot)$ with respect to some baseline measure $\mu$. That is, $X_{k,t}$ has the following conditional density functions

$$ X_{k,t} \mid \tau_1, \ldots, \tau_K, \{X_{l,s}; 1 \leq l \leq K, 1 \leq s \leq t - 1\} \sim \begin{cases} p_{k,t} & \text{if } t \leq \tau_k, \\ q_{k,t} & \text{if } t > \tau_k. \end{cases} \quad (2.1) $$

Remark 1. We assume that the prior distribution for the change points, and the pre- and post-change distributions are known, which is a standard assumption in single-stream Bayesian sequential change detection (e.g., Shiryaev, 1963). Similar assumptions are adopted in recent developments on multi-stream sequential multiple testing (Song and Fellouris, 2019) and
multi-stream sequential change detection (Chen, Zhang and Poor, 2020).

When these distributions are unknown, the current results provide the oracle procedure and theoretical guidance for the development and analysis of the sequential change detection procedures. In addition, the proposed procedure can be extended to handle the unknown distribution scenario via an empirical Bayes approach (see e.g., Efron, 2008; Jiang and Zhang, 2009; Robbins, 1956; Zhang, 2003). Alternatively, we can run the proposed procedure under the worst case model, if such a model can be specified using domain knowledge. This procedure will preserve some properties of the oracle one, when the change point model enjoys certain stochastic ordering properties.

Equation (2.1) provides a general model for change points in parallel data streams. It contains some commonly used models as special cases. We provide two examples below.

**Example 1 (A partially dependent model).** Let $\tau_0$ be a non-negative random variable and $\tau_1, \cdots, \tau_K$ are i.i.d. conditional on $\tau_0$, with conditional distribution $\Pr(\tau_k = m|\tau_0 = m) = \eta$ and $\Pr(\tau_k = \infty|\tau_0 = m) = 1 - \eta$ for $m = 0, 1, \cdots$, and some parameter $\eta \in [0, 1]$.

This model describes the situation where there is a single change point for all of the data streams. After the change point, all or part of the data
2.1 Bayesian Change-point Model for Parallel Streams

streams have a distributional change. If we further let $p_{k,t}$ be the density function of standard normal distribution $N(0,1)$, and $q_{k,t}$ be the density function of $N(\mu,1)$ for some $\mu > 0$. Then this model becomes a Bayesian formulation of the change-point models studied in Mei (2010), Xie and Siegmund (2013), and Chan (2017). An interesting boundary case is $\eta = 1$, where all the change points $\tau_1 = \cdots = \tau_K$ are the same. This case can be viewed as a single change point affecting all the data streams.

**Example 2** (An i.i.d. change-point model). Assume that $\tau_1, \cdots, \tau_K$ are i.i.d. geometrically distributed random variables with $\Pr(\tau_k = m) = \theta(1 - \theta)^m$ for $m = 0, 1, \cdots$ and $\theta \in (0,1)$. In addition, assume that $p_{k,t}(x) = p(x)$ and $q_{k,t}(x) = q(x)$ for all $k,t,x$. This model is referred to as model $M_\alpha$ in the rest of the paper.

We remark that the geometric distribution assumption is commonly adopted in Bayesian change-point detection (see, e.g., Tartakovsky et al., 2014). We adopt this assumption for simplicity as it leads to analytic posterior probabilities, and point out that it can be relaxed to other known distributions. See Section 3.3 for a discussion about the calculation of posterior probabilities.
2.2 Compound Sequential Change-point Detection

We now introduce a compound sequential change-point detection problem, which will be defined through an index set process, $S_t \subset \{1, \ldots, K\}$, where $S_t$ indicates the set of active streams at time $t$. Specifically, if $k \in S_t$, then stream $k$ is active at time $t$; otherwise, it is deactivated. We require the process to satisfy that $S_{t+1} \subset S_t$ for all $t = 1, 2, \ldots$, meaning that a stream is not allowed to be re-activated once turned off. This requirement is consistent with many real-world applications. For example, in standardized educational testing, once an item is found to have leaked, it will be removed from the item pool permanently. At the beginning of data collection (i.e., $t = 1$), all the data streams are active, and thus $S_1 = \{1, \ldots, K\}$.

A sequential detection procedure $S_t$ is defined together with an information filtration, where the definition is inductive. We first let $\mathcal{F}_1 = \sigma(X_{k,1}, k = 1, \ldots, K)$. Then for any $t > 1$, we let $\mathcal{F}_t = \sigma(\mathcal{F}_{t-1}, S_t, X_{k,t}, k \in S_t)$, where $S_t \subset \{1, \ldots, K\}$ is $\mathcal{F}_{t-1}$ measurable. We say $\{\mathcal{F}_t\}_{t=1,2,\ldots}$ is the information filtration, and the index set process $\{S_t\}_{t \geq 1}$ describes a compound sequential change-point detection procedure with respect to this information filtration.

Sometimes, it is more convenient to represent the decision procedure by a random vector $T = (T_1, \ldots, T_K)$, where $T_k \in \mathbb{Z}_+$ is defined as $T_k = \sup\{t : k \in S_t\}$. It is easy to check that $\{T_k = t\} \in \mathcal{F}_t$ for all $t$, and thus $T_k$
2.3 Local False Non-discovery Rate

is a stopping time under the filtration \( \{ \mathcal{F}_t \}_{t=1,2,...} \). The stopping time \( T_k \) indicates the time up to which we collect data from the \( k \)th stream. In other words, starting from time \( T_k + 1 \), the \( k \)th stream is deactivated and its data are no longer collected. The index set at time \( t \) is given by \( S_t = \{ k : T_k \geq t \} \).

The sigma field \( \sigma(X_{k,s \wedge T_k}, s \leq t, k = 1, ..., K) \) is in \( \mathcal{F}_t \), meaning that our information filtration at time \( t \) contains all the information from the streams when they are active. Besides the information from observable data \( X_{k,t} \), the filtration \( \mathcal{F}_t \) also contains information from the decision history, reflected by that \( S_s \) is measurable with respective to \( \mathcal{F}_t \), for all \( s \leq t \).

In what follows, we introduce two compound performance metrics for this sequential decision problem.

### 2.3 Local False Non-discovery Rate

In this sequential decision problem, our primary goal is to control the proportion of post-change streams among the active ones at any time, where a smaller proportion indicates a better overall quality of the active streams. This proportion can be viewed as a False Non-discovery Proportion (FNP) that is often considered in multiple hypothesis testing ([Genovese and Wasserman, 2002](#)), but defined at each time point under the current
2.3 Local False Non-discovery Rate

In the sequential setting, we define the FNP as

\[
\text{FNP}_{t+1}(T) = \frac{\sum_{k \in S_{t+1}} 1(\tau_k < t)}{|S_{t+1}| \lor 1} = \frac{\sum_{k=1}^{K} 1(T_k > t, \tau_k < t)}{\{|\sum_{k=1}^{K} 1(T_k > t)\} \lor 1},
\]

where \( t = 1, 2, ..., a \lor b = \max(a, b) \) and \(|S|\) indicates the size of a set \( S \).

In this definition, \(|S_{t+1}|\) represents the total number of active streams at time \( t + 1 \), and \( \sum_{k \in S_{t+1}} 1(\tau_k < t) \) represents the total number of active post-change streams at time \( t + 1 \). By having \( \lor 1 \) in the denominator, \( \text{FNP}_{t+1}(T) \) is well-defined even when \(|S_{t+1}| = 0\). Finally, we let \( \text{FNP}_1 = 0 \), as \( \tau_k \geq 0 \) for \( k = 1, 2, ..., K \).

Ideally, we would like to control the FNP to be below an acceptable threshold at any time point, which is not always possible as the change points are unknown. As an alternative, we control the Local False Non-discovery Rate (LFNR) which can be viewed as the best estimate of the FNP under the Bayesian sense. The LFNR is defined as

\[
\text{LFNR}_{t+1}(T) = \mathbb{E}(\text{FNP}_{t+1}(T) \mid \mathcal{F}_t), t = 1, 2, \cdots.
\]

Since \( \text{FNP}_1 = 0 \), \( \text{LFNR}_1(T) \) is set to 0.

In what follows, we will focus on sequential change-point detection procedures defined in Section 2.2 under the constraint that \( \text{LFNR}_t(T) \leq \alpha \) for all \( t \) for some pre-specified level \( \alpha \) (e.g., \( \alpha = 1\% \)). More precisely, for a given \( \alpha \in (0, 1] \), we consider the following class of compound sequential
change-point detection procedures which controls the LFNR to be below or equal to $\alpha$ at any time, $\mathcal{T}_\alpha = \{ T \in \mathcal{T} : \text{LFNR}_t(T) \leq \alpha \text{ a.s.}, \text{for all } t = 1, 2, \cdots \}$, where $\mathcal{T}$ denotes the entire set of compound sequential change-point detection procedures.

We provide a few remarks. First, $\text{LFNR}_{t+1}(T)$ is a random variable measurable with respect to $\mathcal{F}_t$. It depends on both the change-point model and the detection procedure $T$. Second, it is easy to observe that $\mathbb{E}(\text{FNP}_t(T)) \leq \alpha$ for every $t$, for any $T \in \mathcal{T}_\alpha$. That is, the unconditional expectation of FNP is also controlled at the same $\alpha$ level. Finally, by replacing $\tau_k < t$ with $\tau_k \geq t$ and $S_{t+1}$ with $S_t \setminus S_{t+1}$ in the definition of FNP, we can similarly define the false discovery proportion (FDP) and local false discovery rate (LFNR) as $\text{FDP}_{t+1} = (|S_t \setminus S_{t+1}| \lor 1)^{-1} \sum_{k \in S_t \setminus S_{t+1}} 1(\tau_k \geq t)$ and $\text{LFDR}_{t+1} = \mathbb{E}(\text{FDP}_{t+1}(T) | \mathcal{F}_t)$. The main difference between FNR- and FDR-type risk measures is whether focusing on the remaining streams or the streams to be deactivated. Specifically, the LFNR focuses on the remaining streams and thus is a preferred measure if the goal is to control the overall quality of the active data streams (e.g., controlling the proportion of leaked items in the item pool of an educational test). On the other hand, the LFDR is calculated based on the streams to be detected and deactivated. It is thus a better metric if the goal is to control the accuracy among the
2.4 Stream Utilization and Optimality Criteria

detected streams.

2.4 Stream Utilization and Optimality Criteria

Given a level $\alpha$, the class $\mathcal{T}_\alpha$ has many elements. We propose to compare them based on their overall utilization of data streams. More precisely, we consider the following measure

$$U_t(\mathcal{T}) = \sum_{s=1}^{t} |S_s| = \sum_{s=1}^{t} \sum_{k=1}^{K} \mathbf{1}(T_k \geq s),$$

where $\mathcal{T} = (T_1, \cdots, T_K)$ is a sequential change-point detection procedure and $U_t(\mathcal{T})$ is the total number of data points collected from the beginning to time $t$.

For two sequential procedures $\mathcal{T}$ and $\mathcal{T}'$ in $\mathcal{T}_\alpha$, we say $\mathcal{T}$ is more efficient than $\mathcal{T}'$ at time $t$ if $\mathbb{E}(U_t(\mathcal{T})) \geq \mathbb{E}(U_t(\mathcal{T}'))$. In addition, we say $\mathcal{T}$ is uniformly more efficient than $\mathcal{T}'$ if $\mathbb{E}(U_t(\mathcal{T})) \geq \mathbb{E}(U_t(\mathcal{T}'))$, for all $t = 1, 2, \ldots$. Following the previous discussion, our goal becomes developing an efficient procedure in terms of stream utilization, under the constraint that LFNR is below a pre-specified $\alpha$ level all the time. Specifically, we consider the following two optimality criteria, which will guide our development of compound detection procedures to be discussed in Section 3.

**Definition 1** (Uniform optimality). We say a sequential change-point detection procedure $\mathcal{T} \in \mathcal{T}_\alpha$ is uniformly optimal in $\mathcal{T}_\alpha$, if $\mathcal{T}$ is uniformly more
2.4 Stream Utilization and Optimality Criteria

efficient than $T'$, for any $T' \in \mathcal{T}_a$. That is, $E(U_t(T)) = \sup_{T' \in \mathcal{T}_a} E(U_t(T'))$, for all $t = 1, 2, ...$

Ideally, we would like to find this uniformly optimal procedure. However, such a procedure does not necessarily exist as the most efficient procedure at one time point may be less efficient than another procedure at a different time point. Thus, we also consider a weaker version of optimality, which is referred to as the local optimality at a given time point.

**Definition 2 (Local optimality).** Given $\mathcal{F}_t$ at time $t$, we say the choice of $S_{t+1} \subset S_t$ is locally optimal at time $t+1$, if $S_{t+1}$ is $\mathcal{F}_t$ measurable, $E\left(\frac{\sum_{k \in S_{t+1}} I(\tau_k < t)}{|S_{t+1}|} | \mathcal{F}_t\right) \leq \alpha$, and $|S_{t+1}| \geq |S|$ a.s. for any other $S \subset S_t$ that is also $\mathcal{F}_t$ measurable and satisfies $E\left(\frac{\sum_{k \in S} I(\tau_k < t)}{|S|} | \mathcal{F}_t\right) \leq \alpha$.

Note that the local optimality criterion only looks at one step forward. A procedure is locally optimal if it maximizes the stream utilization in the next step. Achieving local optimality in each step does not necessarily lead to uniform optimality and a uniformly optimal procedure does not necessarily exist; see Example 3 in Section 4.

We provide a discussion on the choice of the performance metric. The expected stream utilization measure is most sensible, if the active streams have the same utility at any time point, whether having changed or not. This approximately holds for the application to item pool monitoring in
2.4 Stream Utilization and Optimality Criteria

educational testing, when the leaked items are only accessible by a small proportion of test takers, in which case the utilities of the leaked and unleashed items are similar.

A closely related performance measure is the cumulative number of detections $\text{CD}_t = K - |S_t|$ at each time point. This performance metric is sensible when each detection (and thus deactivation) is associated with a fixed cost, in which case the goal becomes to minimize the total cost up to each time point. This metric may also be sensible for the application to item pool monitoring in educational testing. That is, once an item is deactivated, a new item needs to be developed as a replacement, for which the cost is approximately the same across items.

In some applications, it may be more sensible to consider a performance metric based on the utilization of pre-change streams, defined as $\text{RL}_t(T) = \sum_{k=1}^{K} (T_k \wedge \tau_k \wedge t)$. The expectation of this metric can be viewed as an online-and-compound version of the average run length to false alarm (Lorden, 1971), a classical performance metric for sequential change detection.

As will be shown in Section 5, similar optimality results hold based on the performance measures $\text{RL}_t(T)$ and $\text{CD}_t(T)$. 
3. Proposed Method

3.1 One-step Update Rule

We first propose a one-step update rule for controlling the LFNR to be below a pre-specified level. Let a certain sequential change-point detection procedure be implemented from time 1 to \( t \), and \( \mathcal{F}_t \) be the current information filtration. A one-step update rule decides the index set \( S_{t+1} \subset S_t \) based on the up-to-date information \( \mathcal{F}_t \), so that the LFNR at time \( t + 1 \) is controlled below the pre-specified level \( \alpha \). In the meantime, this update rule tries to maximize the size of \( S_{t+1} \) to optimize stream utilization. The details of the proposed one-step update rule is described in Algorithm 1 below.

This algorithm contains three steps. In the first step, the stream-specific posterior probabilities are sorted in an ascending order. We tend to select the streams with small posterior probabilities into \( S_{t+1} \), as they are more likely to be pre-change streams. In the second step, we calculate the cumulative averages of the sorted posterior probabilities. Finally, we find the largest \( n \) such that the corresponding cumulative average is no greater than \( \alpha \). The corresponding streams will be kept in \( S_{t+1} \) and the rest will be deactivated. The cumulative average of the \( n \) streams gives the LFNR for \( S_{t+1} \).

The proposed one-step update rule controls the LFNR under the general
Algorithm 1 One-step update rule.

**Input:** Threshold $\alpha$, the current index set $S_t$, and posterior probabilities $\left( W_{k,t} \right)_{k \in S_t}$, where $W_{k,t} = \Pr(\tau_k < t | \mathcal{F}_t)$.

1: Sort the posterior probabilities in an ascending order. That is, $W_{k_1,t} \leq W_{k_2,t} \leq \cdots \leq W_{k_{|S_t|},t}$, where $S_t = \{k_1, ..., k_{|S_t|}\}$. To avoid additional randomness, when there exists a tie ($W_{k_i,t} = W_{k_{i+1},t}$), we require $k_i < k_{i+1}$.

2: For $n = 1, ..., |S_t|$, define $R_n = \frac{\sum_{i=1}^{n} W_{k_i,t}}{n}$, and define $R_0 = 0$.

3: Find the largest $n \in \{0, 1, ..., |S_t|\}$ such that $R_n \leq \alpha$.

**Output:** $S_{t+1} = \{k_1, ..., k_n\}$ if $n \geq 1$ and $S_{t+1} = \emptyset$ if $n = 0$.

model in (2.1), as formally described in Proposition 1.

**Proposition 1.** Suppose that we obtain the index set $S_{t+1}$ using Algorithm 1, given the index set $S_t$ and information filtration $\mathcal{F}_t$ at time $t$. Then the LFNR at time $t + 1$ satisfies $\mathbb{E}\left( \frac{\sum_{k \in S_{t+1}} 1(\tau_k < t)}{|S_{t+1}|} | \mathcal{F}_t \right) \leq \alpha$.

3.2 Proposed Compound Sequential Change-point Detection Procedure

The proposed procedure adaptively applies the above one-step update rule. That is, at each time point $t$, we select the active set $S_{t+1}$ using Algorithm 1, given the information available at time $t$ including the current active set.
3.3 Calculation of Posterior Probabilities

$S_t$ and the corresponding posterior probabilities $(W_{k,t})_{k \in S_t}$. This method is formally described in Algorithm 2 below. We will later refer to this procedure as $T^*$.

**Algorithm 2** Proposed Procedure ($T^*$).

**Input:** Threshold $\alpha$.

1. Let $S_1 = \{1, \cdots, K\}$ and $W_{k,1} = \text{Pr}(\tau_k < 1 | F_1)$ for $k \in S_1$.

2. For $t = 1, 2, 3, \cdots$, input $\alpha$, $S_t$ and $(W_{k,t})_{k \in S_t}$ to Algorithm 1 and obtain $S_{t+1}$ and $W_{k,t+1} = \text{Pr}(\tau_k < t + 1 | F_{t+1})$ for $k \in S_{t+1}$, where $F_{t+1} = \sigma(F_t, S_{t+1}, X_{k,t+1}, k \in S_{t+1})$.

**Output:** $\{S_t\}_{t=1,2,\cdots}$, or equivalently, $T^* = (T_1, \cdots, T_K)$, where $T_k = \sup\{t : k \in S_t\}$.

Making use of Proposition 1, it is easy to show that the proposed procedure controls the LFNR at each step under the general change-point model described in (2.1). This result is summarized in Proposition 2.

**Proposition 2.** Let $T^*$ be defined in Algorithm 2. Then, $T^* \in T_\alpha$.

3.3 Calculation of Posterior Probabilities

The proposed update rule relies on the posterior probability $W_{k,t} = \text{Pr}(\tau_k < t | F_t)$, which is the conditional probability of the change point has occurred to stream $k$ before the current time point $t$. In general, this posterior probabil-
3.3 Calculation of Posterior Probabilities

ity depends on data from all the streams and thus its evaluation may be computationally intensive when $K$ is large and $(\tau_1, \cdots, \tau_K)$ has a complex dependence structure. In that case, a Markov chain Monte Carlo methods may be needed for evaluating this posterior probability. Under the special case of model $\mathcal{M}_s$ described in Example 2, this posterior probability is easy to evaluate using an iterative update rule as given in Lemma 1 below.

**Lemma 1.** Under model $\mathcal{M}_s$ described in Example 2, $W_{k,0} = 0$ for $1 \leq k \leq K$ and $W_{k,t}$ can be computed using the following update rule for $1 \leq k \leq K$,

$$W_{k,t+1} = \begin{cases} \frac{q(X_{k,t+1})/p(X_{k,t+1})}{(1-\theta)(1-W_{k,t})/(\theta+(1-\theta)W_{k,t})+q(X_{k,t+1})/p(X_{k,t+1})} & \text{if } 1 \leq t \leq T_k - 1, \\ W_{k,T_k} & \text{if } t \geq T_k. \end{cases}$$

(3.4)

We point out that the iteration in the above lemma is a slight modification of a classical result for Bayesian sequential change-point detection (Shiryaev 1963). Indeed, with a single data stream, the statistic $W_{k,t}$ is known to be the test statistic for the Shiryaev procedure, a sequential change-point detection procedure that has been proven the Bayes rule for minimizing the average detection delay while controlling the probability of false alarm. A slight difference here is that $W_{k,t}$ stays the same after $T_k$ due to the control process that deactivates data streams.
4. Theoretical Results

4.1 Optimality Results

In what follows, we establish optimality results for the proposed one-step update rule and the proposed procedure $T^*$, under the optimality criteria given in Section 2.4. The proposed update rule is locally optimal under the general change-point model (2.1), following Definition 2 for local optimality.

**Proposition 3.** Given LFNR level $\alpha$ and information filtration $\mathcal{F}_t$, the index set $S_{t+1}$ given by Algorithm 1 is locally optimal at time $t+1$.

In general, having local optimality in each step does not necessarily lead to uniform optimality and a uniformly optimal procedure may not even exist. However, Theorem 1 below shows that a uniformly optimal procedure exists under change-point model $\mathcal{M}_s$ and furthermore the proposed procedure is uniformly optimal. In other words, in this case, a myopic decision rule that maximizes the next-step stream utilization under the LFNR constraint is also uniformly optimal throughout time.

**Theorem 1.** Under model $\mathcal{M}_s$, the proposed method $T^*$ is uniformly optimal in $T_\alpha$.

Although model $\mathcal{M}_s$ seems relatively simple, the uniform optimality result established in Theorem 1 is highly non-trivial and requires non-
standard technical tools for the proof, such as the monotone coupling on a partially ordered space for comparing stochastic processes of different dimensions. Part of the challenge is from the compound nature of the problem. Below we intuitively explain why standard techniques for justifying the optimality of single-stream sequential change-point detection methods do not apply to our problem. Heuristically, for a given $t$, a larger value of $W_{k,t} = \Pr(\tau_k \leq t - 1|\mathcal{F}_t)$ suggests a higher chance that a change point has already taken place for the $k$th data stream. This is why the proposed procedure chooses to detect streams with the largest posterior probabilities $W_{k,t}$. Indeed, this update rule has been proven optimal for a single change detection problem under a Bayesian formulation (Shiryaev, 1963) and is locally optimal according to Proposition 3. However, the local optimality does not necessarily imply uniform optimality. To show uniform optimality, one needs to look into the future. More specifically, we need to deal with the situation where a large value of $W_{k,t}$ is due to random noise and the posterior probability of the stream may become small at a future time point. In other words, supposing that $W_{k_1,t} > W_{k_2,t}$, we need to show that it is more optimal to detect $k_1$ than $k_2$ at time $t$ under our optimality criteria, even though $W_{k_1,t+s} < W_{k_2,t+s}$ can happen with high probability for some $s > 0$. To establish the uniform optimality, we need the $W_{k,t}$ process
generated by the proposed procedure to have some stochastically monotone property. A proof sketch for Theorem 1 and a complete proof are given in the supplementary material, where some new techniques are established for the monotone coupling of stochastic processes on a partially ordered space.

In Theorem 1, the assumptions required by the model $M_s$ may be relaxed. By examining the current proof and the fact that the updating rule for the posterior probabilities can be extended to non-geometric priors, we believe that the uniform optimality can still be proved, if the change points are i.i.d. following some prior distribution with support $\{0, 1, 2, \ldots\}$, for example, a negative binomial distribution. Similarly, the optimality results may be extended to the case where $p_{k,t} = p_t$ and $q_{k,t} = q_t$ for some time-dependent functions $p_t$ and $q_t$. On the other hand, we believe that it is necessary to assume the data streams $\{X_{k,t}\}_{t \geq 1}$ are identically distributed for different $k$ for the proposed method to be uniformly optimal. Indeed, if the processes $\{X_{k,t}\}_{t \geq 1}$ are not identically distributed, then there may not exist a uniformly optimal procedure. One such example is given below.

**Example 3** (Non-existence of uniformly optimal procedure). Let $K = 4$ and $\tau_k$s be independent, for $k = 1, 2, 3, 4$. The change-point distributions satisfy $\Pr(\tau_k \geq 4) = 0$ for $k = 1, 2, 3, 4$. For $m = 0, 1, 2, 3$ and $k = 1, 2, 3, 4$, the probabilities $\Pr(\tau_k = m)$ are given below. In addition, let $X_{k,t} \mid t \leq \tau_k \sim$
4.1 Optimality Results

Bernoulli(0.5) and \( X_{k,t} | t > \tau_k \sim \text{Bernoulli}(0.51) \) for \( k = 1, 2, 3, 4 \). Finally, we set \( \alpha = 0.34 \). This model is not in \( \mathcal{M}_s \), as the change points are not identically distributed. Enumerating all elements in \( \mathcal{T}_\alpha \), we have

| \( \Pr(\tau_k = m) \) | \( m = 0 \) | \( m = 1 \) | \( m = 2 \) | \( m = 3 \) |
|----------------------|----------|----------|----------|----------|
| \( k = 1 \)         | 0.1      | 0        | 0        | 0.9      |
| \( k = 2 \)         | 0.4      | 0.6      | 0        | 0        |
| \( k = 3 \)         | 0.43     | 0.57     | 0        | 0        |
| \( k = 4 \)         | 0.55     | 0        | 0        | 0.45     |

However, there is no such a sequential procedure maximizing stream utilization at both \( t = 2 \) and \( t = 4 \). Consequently, there does not exist a uniformly optimal procedure in this example. The calculation for this example is provided in the supplementary material.

Remark 2. We remark that a similar algorithm can be given for controlling LFDR\(_t\) and in the meantime achieving a similar local optimality property. However, as the LFDR is calculated based on the stopped data streams rather than the active ones, the current techniques for proving uniform optimality no longer apply. The theoretical properties of the LFDR-control procedure is left for future investigation.
4.2 Asymptotic Theory

In modern multi-stream change-point detection problems, the number of data streams can be large. To enhance our understanding of the proposed method in large-scale applications, we study the asymptotic properties of the proposed method when the number of streams $K$ goes to infinity.

We first study the structure of $T^*_t$ under model $\mathcal{M}_s$. We define the following process

$$V_0 = 0 \text{ and } V_{t+1} = \frac{q(X_{1,t+1})/p(X_{1,t+1})}{(1 - \theta)(1 - V_t)/((\theta + (1 - \theta)V_t) + q(X_{1,t+1})/p(X_{1,t+1}))},$$

where parameter $\theta$ and densities $p(\cdot)$ and $q(\cdot)$ are given by the model $\mathcal{M}_s$. We further define $\lambda_0 = 1$ and

$$\lambda_t = \sup \left\{ \lambda : \lambda \in [0, 1] \text{ and } \mathbb{E}(V_t | V_t \leq \lambda, V_s \leq \lambda_s, 0 \leq s \leq t - 1) \leq \alpha \right\}$$

(4.5)

for $t = 1, 2, \cdots$. Theorem 2 below shows that when $K$ grows to infinity, the proposed procedure $T^*_t$ converges to a limiting procedure $T^t$, for which the choice of index set $S_{t+1}^t$ is given by $S_{t+1}^t = \{k \in S_t^t : W_{k,t} \leq \lambda_t \}$. It suggests that when $K$ is large, we can replace the proposed procedure $T^*$ by the limiting procedure $T^t$. The latter is computationally faster, as the thresholds $\lambda_t$ can be computed offline and the updates for streams can be computed in parallel. We make the following technical assumption.
A1. For $Z_1$ following density function $p(\cdot)$ and $Z_2$ following density function $q(\cdot)$, the likelihood ratios $q(Z_1)/p(Z_1)$ and $q(Z_2)/p(Z_2)$ have continuous and strictly positive density functions over $\mathbb{R}_+$ (with respect to the Lebesgue measure).

The above assumption is easily satisfied by continuous random variables. For example, it is satisfied when $p(\cdot)$ and $q(\cdot)$ are two normal density functions with different means and/or variances.

**Theorem 2.** Assume that model $\mathcal{M}_s$ holds and Assumption A1 is satisfied. To emphasize the dependence on $K$, we denote the proposed procedure by $T^*_K$, the corresponding information filtration at time $t$ by $\mathcal{F}^*_K,t$, and the index set at time $t$ by $S^*_K,t$. Then, the following results hold for each $t \geq 1$.

1. $\lim_{K \to \infty} \hat{\lambda}_{K,t} = \lambda_t$ a.s., where $\hat{\lambda}_{K,t} = \max\{W_{k,t} : k \in S^*_K,t+1\}$ is the threshold used by $T^*_K$.

2. $\lim_{K \to \infty} \text{LFNR}_{t+1}(T^*_K) = \mathbb{E}(V_t \mid V_s \leq \lambda_s, 0 \leq s \leq t)$ a.s. Moreover,

$$\mathbb{E}(V_t \mid V_s \leq \lambda_s, 0 \leq s \leq t) = \begin{cases} 1 - (1 - \theta)^t, & t < \frac{\log(1-\alpha)}{\log(1-\theta)}; \\ \alpha, & t \geq \frac{\log(1-\alpha)}{\log(1-\theta)}. \end{cases} \quad (4.6)$$

3. $\lim_{K \to \infty} K^{-1}|S^*_K,t+1| = \Pr (V_1 \leq \lambda_1, \ldots, V_t \leq \lambda_t)$ a.s.

We remark that according to the definition of $\lambda_t$ and the second statement of Theorem 2, when $t < \log(1-\alpha)/\log(1-\theta)$, $\lim_{K \to \infty} \text{LFNR}_{t+1}(T^*_K) < \alpha$. 

4.2 Asymptotic Theory

a.s. and no deactivation of streams is needed yet. Otherwise, \( \lim_{K \to \infty} \text{LFNR}_{t+1}(T^*_K) = \alpha \) a.s., which is achieved by deactivating suspicious streams.

We also provide asymptotic theory for a special case of Example 1 when the change points are completely dependent, i.e., \( \tau_1 = \cdots = \tau_K = \tau_0 \). We make the following assumption.

A2. For \( Z_1 \) following density \( p(\cdot) \) and \( Z_2 \) following density \( q(\cdot) \), the density functions satisfy\( \mathbb{E} \left( \log \frac{p(Z_1)}{q(Z_1)} \right) > 0, \mathbb{E} \left( \log \frac{q(Z_2)}{p(Z_2)} \right) > 0, \mathbb{E} \left( \log \frac{p(Z_1)}{q(Z_1)} \right)^2 < \infty, \) and \( \mathbb{E} \left( \log \frac{q(Z_2)}{p(Z_2)} \right)^2 < \infty \).

Note that \( \mathbb{E} \left( \log (p(Z_1)/q(Z_1)) \right) \) and \( \mathbb{E} \left( \log (q(Z_2)/p(Z_2)) \right) \) are the Kullback-Leibler divergence between \( p(\cdot) \) and \( q(\cdot) \). Requiring them to be positive is the same as requiring \( p(\cdot) \) and \( q(\cdot) \) to be densities of two different distributions.

**Theorem 3.** Suppose that data follow a special case of the model given in Example 2 when \( \eta = 1 \) and \( \tau_0 \sim \text{Geom}(\theta) \), and Assumption A2 holds. Let

\[
W_t = \Pr(\tau_0 < t \mid X_{k,s}, 1 \leq k \leq K, 1 \leq s \leq t), \quad T = \min\{t : W_t > \alpha\}.
\]

Then, \( T^*_K = (T, \cdots, T) \). Moreover, the following asymptotic results hold.

1. \( \lim_{K \to \infty} (T - \tau_0) = 1 \) a.s.,

2. \( \lim_{K \to \infty} \text{LFNR}_{t+1}(T^*_K) = 0 \) a.s.,
3. \( \lim_{K \to \infty} K^{-1} |S_{K,t+1}^*| = 1(\tau_0 \geq t) \) a.s.

According to the above theorem, the detection time in the proposed procedure is the same for all the data streams. This detection rule is the same as the classical Shiryaev procedure [Shiryaev, 1963] for a single data stream. It thus shares all the optimality properties of the Shiryaev procedure. We further remark that the last limit in the above theorem is non-degenerate in the sense that it is a Bernoulli random variable, rather than a constant as in Theorem 2.

5. Additional Theoretical Results

In this section, we give extensions of Theorem 1. We first extend the uniform optimality result in Theorem 1 to two other performance measures, \( RL_t(\mathbb{T}) = \sum_{k=1}^{K} (T_k \wedge \tau_k \wedge t) \) and \( CD_t = K - |S_t| \), as discussed in Section 2.4.

**Theorem 4.** Under model \( \mathcal{M}_s \), the following equations hold for all \( t \),

\[
\mathbb{E}(RL_t(\mathbb{T}^*)) = \sup_{\mathbb{T} \in \mathbb{T}_a} \mathbb{E}(RL_t(\mathbb{T})) \text{ and } \mathbb{E}(CD_t(\mathbb{T}^*)) = \inf_{\mathbb{T} \in \mathbb{T}_a} \mathbb{E}(CD_t(\mathbb{T})). \quad (5.7)
\]

We then extend Theorem 1 by investigating a comparison between an arbitrary sequential procedure in \( \mathbb{T}_a \) and a procedure which switches from this procedure to the proposed procedure after a certain time point. This result provides further insights into the proposed procedure. Specifically,
we use $T^A \in T_\alpha$ to denote an arbitrary sequential procedure which controls
the LFNR. We further consider a procedure $T^{AP_{t_0}}$, which takes the same
procedure as $T^A$ for $t = 1, \ldots, t_0$. After time $t_0 + 1$ and onwards, each step of
$T^{AP_{t_0}}$ follows the proposed update rule in Algorithm[2]. Theorem[5] compares
four sequential procedures, including $T^A$, $T^{AP_{t_0}}$, $T^{AP_{t_0+1}}$, and $T^*$.

**Theorem 5.** Let $T^A \in T_\alpha$ be an arbitrary sequential procedure. Further
let $T^{AP_{t_0}}$ and $T^{AP_{t_0+1}}$ be the switching procedures described above, with
switching time $t_0$ and $t_0 + 1$, respectively, for some $t_0 \geq 0$. Then, for all
t = 1, 2, \ldots, $T^{AP_{t_0}}, T^{AP_{t_0+1}} \in T_\alpha$ and under model $M_s$

$$
\mathbb{E}(U_t(T^A)) \leq \mathbb{E}(U_t(T^{AP_{t_0+1}})) \leq \mathbb{E}(U_t(T^{AP_{t_0}})) \leq \mathbb{E}(U_t(T^*)) .
$$

The above theorem implies that, under model $M_s$, $T^{AP_{t_0}}$ is uniformly
better than $T^A$. It also suggests to switch to the proposed procedure as soon
as possible, if one cannot use the proposed procedure at the beginning due
to practical constraints. Theorems[1] and [5] are implied by the next theorem.

**Theorem 6.** Suppose that model $M_s$ holds. For any $t_0, s \geq 0$ and any
sequential detection procedure $T^A \in T_\alpha$, let $F_t^A$ be the information filtration
and $S_t^A$ be the set of active streams at time $t$ given by $T^A$. Then,

$$
\mathbb{E} \left[ |S^A_{t_0+s}||F^A_{t_0} \right] \leq \mathbb{E} \left[ |S^{AP_{t_0}}_{t_0+s}||F^A_{t_0} \right] \text{ a.s.} \quad (5.8)
$$
6. Numerical Experiment

We evaluate the proposed procedure via a simulation study under the change-point model $\mathcal{M}_s$. Two stream sizes $K = 50$ and 500 are considered, representing problems of different scales. For all the data streams, we let the pre- and post-change distributions be $N(0, 1)$ and $N(1, 1)$, respectively. We consider two settings for the change-point distribution, with $\theta = 0.01$ and 0.05 in the geometric distribution, respectively. We set the threshold to be $\alpha = 0.05$ for the control of LFNR. The combinations of $K$ and $\theta$ lead to four different settings. For each setting, we run 5000 independent replications.

We consider two procedures, including (1) the adaptive procedure given in Algorithm 2 and (2) a procedure in which a stream $k$ is deactivated if the posterior probability $W_{k,t}$ is greater than the non-adaptive threshold $\lambda_t$ (see (4.5)) given by the asymptotic results. The non-adaptive threshold $\lambda_t$ is approximated via a simulation with 1,000,000 streams.

We evaluate these procedures by (1) mean FNP, (2) mean LFNR, (3) mean number of active streams, and (4) mean stream utilization, at each time point. These values are obtained by averaging over the 5000 independent replications. For example, for each simulation, we can calculate the FNP at each time point following equation (2.2). The mean FNP at each time point is then calculated by averaging the corresponding FNP values from
Figure 1: Results under the setting when $K = 50$ and $\theta = 0.01$. Panels (a) through (d) correspond to the four metrics, (1) mean FNP, (2) mean LFNR, (3) mean number of active streams, and (4) mean stream utilization, respectively.

The 5000 independent simulations under each setting. The other metrics are calculated similarly. The results are given in Figures 1 through 4 that correspond to the settings (1) $K = 50$, $\theta = 0.01$, (2) $K = 50$, $\theta = 0.05$, (3) $K = 500$, $\theta = 0.01$, and (4) $K = 500$, $\theta = 0.05$, respectively. We discuss these results below.

First, for the proposed adaptive procedure, the mean FNP and mean LFNR are always below the 0.05 threshold under all the four settings, suggesting that the risk of the active streams is well-controlled at the aggregate level; see Panels (a) and (b) of the figures. The control of these quantities is a direct result of the proposed procedure controlling LFNR at every time point. More specifically, when $\theta = 0.05$, the data streams change relatively more quickly than the case when $\theta = 0.01$. In that case, the proportion of post-change streams quickly exceed 0.05 and the proposed
Figure 2: Results under the setting when $K = 50$ and $\theta = 0.05$. The four panels show the same metrics as in Figure 1.

Figure 3: Results under the setting when $K = 500$ and $\theta = 0.01$. The four panels show the same metrics as in Figure 1.

Figure 4: Results under the setting when $K = 500$ and $\theta = 0.05$. The four panels show the same metrics as in Figure 1.
procedure controls this proportion to be slightly below 0.05 by deactivating
the ones with the highest post-change posterior probabilities. As time goes
on, the mean FNP will decay towards zero, as the number of active streams
decays to zero; see Panels (c) and (d) of Figures 2 and 4. When $\theta = 0.01$,
the data streams change at a much slower rate. Thus, at the beginning, the
proportion of post-change streams among the active ones tends to be smaller
than 0.05 and the proposed procedure does not tend to detect and deactivate
any streams. When the proportion of post-change streams accumulates to
be above 0.05, the proposed procedure starts to deactivate changed streams
to control the proportion to be around the targeted level. As change points
occur more slowly, the number of active streams at any given time point
tends to be larger than that when $\theta = 0.05$. See Figures 1 and 3 for more
details.

Second, as we can see from Panels (a) and (b) of the figures, the non-
adaptive procedure based on the asymptotic theory also controls the mean
FNP and the mean LFNR to be near or below the targeted level, though
the mean FNP may be slightly larger than the targeted level occasionally
under the settings when $K = 50$. It tends to be slightly more aggressive
than the adaptive procedure, because the LFNR can sometimes exceed the
targeted threshold $\alpha$. Overall, the non-adaptive procedure also performs
well, in the sense that it tends to control FNR at the targeted level \( \alpha \) (i.e. the expected value of LFNR) at all time points, even though the LFNR itself is not exactly controlled.

Finally, we see that the two procedures tend to perform more similarly when the number of active streams is larger, as the non-adaptive procedure is the limiting case of the adaptive procedure when the number of streams grows to infinity. More specifically, comparing the setting when \( K = 500 \) (Figures 3 and 4) with that when \( K = 50 \) (Figures 1 and 2), we see that the two procedures are closer to each other when \( K = 500 \). For the same value of \( K \), the two procedures tend to be more similar under the setting when \( \theta = 0.01 \) than that when \( \theta = 0.05 \), as data streams change more slowly and thus there tend to be more active streams at every time point when \( \theta = 0.01 \). Moreover, for each setting, the two procedures tend to behave more similarly when \( t \) is smaller, as the number of active streams decays with time \( t \).

7. Discussions

Motivated by real-world applications from various fields including education, engineering, and finance, we propose a compound decision framework for Bayesian sequential change-point detection in parallel data streams. An
easy-to-implement procedure is proposed, for which theoretical properties are established. Specifically, under a class of change-point models, the proposed procedure is shown to be uniformly optimal in a non-asymptotic sense. Numerical experiments show that the proposed procedure can accurately control the aggregated risk of active streams.

The current work can be extended along several directions. First, different optimality criteria may be considered and the proposed procedure can be extended accordingly. For example, different streams may have different weights due to their unequal importance in practice. In that case, more general definitions of local false non-discovery rate and stream utilization measure can be given, for which a tailored sequential procedure can be derived.

Second, in some real applications, the change-point distribution and the distributions for pre- and post-change data may not be known in advance. This problem may be handled by parameterizing the pre- and post-change distributions and then use a full or empirical Bayes approach that combines the proposed procedure with sequential estimation of the unknown parameters. Optimality theory may be established when the number of streams $K$ goes to infinity.

Third, optimal sequential procedures remain to be developed under
reasonable models for dependent change points. In particular, in many multi-stream change detection problems, the change points may be driven by a low-dimensional latent process, which can be described by a dynamic latent factor model. Several questions remain to be answered under such a change-point model, including the existence of a uniformly optimal procedure and the construction of the uniformly optimal procedure if it exists.

Finally, a more general setting may be considered that allows new data streams to be added dynamically. For example, in educational testing, once an item is removed from the item pool, a new one needs to be developed to maintain the size of the pool. The inclusion of new data streams changes the information filtration. Under the new information filtration which contains information from both the original and new streams, a locally optimal procedure can be developed under similar optimality criteria. However, it is unclear whether this procedure is still uniformly optimal. This problem is worth future investigation.
