Heralded single photons are prepared at a rate of ~100 kHz via conditional measurements on polarization-nondegenerate biphotons produced in a periodically poled KTP crystal. The single-photon Fock state is characterized using high frequency pulsed optical homodyne tomography with a fidelity of (57.6 ± 0.1)%.

The ability to produce single-photon states is of importance for optical quantum computation [1], quantum cryptography [2], and quantum state engineering [3]. Many of these applications require the photons to be generated with a high fidelity in a pure, well-defined spatiotemporal mode. This requirement can be approached by heralded single photons prepared via conditional measurements on biphons produced due to spontaneous parametric down-conversion (SPDC) [4, 5]. In this method, photon pairs produced in a nondegenerate optical parametric amplifier are split into two channels: trigger and signal. A single spatiotemporal mode is selected in the trigger channel and subjected to measurement with a single-photon counting module (SPCM). A detection event heralds preparation of the single photon in the conjugate spatiotemporal mode of the signal channel [6, 7].

A significant disadvantage of heralded photons is that they are not prepared on demand. The bimodal state of light produced due to each pump pulse (we specialize to the pulsed case) obeys thermal statistics:

|Ψ⟩ ≈ (1 − γ2) (|0, 0⟩ + γ |1, 1⟩ + γ2 |2, 2⟩ + ...),

where the numbers refer to Fock states in the signal and trigger channels and γ is proportional to the pump field amplitude as well as the nonlinear susceptibility of the down-conversion medium. In the weak pump regime (γ ≪ 1), a trigger photon detection event indicates that the pulse in the signal channel contains a single photon. The probability of this event scales as ∝ γ2. If multiple photons need to be generated from n heralded sources simultaneously, the probability scales as ∝ γ2n, which results in unpractically long data acquisition times. A higher pump intensity increases the biphonon production rate, but leads, with non-ideal photon detectors, to a spurious multiphoton component in the signal, and thus to reduced fidelities. A compromise between these two regimes is facilitated by higher pump pulse repetition frequencies. In this way, a reasonably high photon creation rate can be reached while maintaining a sufficiently low ratio between (n + 1)- and n-photon events. More frequent pump pulses however imply a reduced optical energy per pulse, which can be compensated by using novel materials with high nonlinear susceptibilities. Additionally, the quantum state measurement optoelectronics must be sufficiently fast to distinguish between neighboring laser pulses.

In this Letter, we report homodyne tomography [8] of the single-photon Fock state |1⟩ generated under such intermediate conditions. The preparation rate is on the scale of 100 kHz with a pump pulse frequency of 76 MHz. This means, on one hand, that the two- and three-photon preparation rates are on the scale of 100 and 0.1 Hz, respectively, which is not prohibitively low. On the other hand, the fraction of multiphoton events heralded as single photons is on the order of 1% (assuming a 10% trigger photon detection efficiency), which is acceptable for most applications. A particularly attractive feature of our experiment is that the amount of data sufficient for reliable state reconstruction is acquired within a fraction of a second, permitting on-the-fly optimization of the setup.

Our setup can be compared with that described by Ourjoumtsev et al. [9]. In that experiment, a cavity dumped Ti:Sapphire laser was employed to increase the pump intensity at the cost of decreasing the repetition frequency of the pump pulses to 800 kHz. Preparation rates of ~4500 Hz and ~15 Hz were reported for Fock states |1⟩ and |2⟩, respectively.

Our apparatus is based on Ref. [6] and displayed in...
A mode-locked Ti:Sapphire laser (Coherent Mira 900) emitted transform-limited pulses at ~790 nm with a repetition rate of 76 MHz and a pulse width of ~1.7 ps. Most of the light was frequency doubled in a single pass through a 17 mm long LBO crystal, yielding typically ~75 mW average second harmonic power after spatiotemporal filtering (f1). This field was coupled into a 2-mm long periodically poled potassium-titanyl phosphate (PPKTP) crystal to pump type-II collinear SPDC. The lengths of the crystals were chosen so that the group velocity dispersion would not lead to significant changes of the pulse width in both nonlinear transformations.

The generated photon pair was separated into the signal and trigger channels according to the photons’ polarizations using a λ/2 plate and a polarizing beam splitter (PBS). A spatiotemporal mode for the trigger photons was selected with a 0.3-nm wide spectral filter (f2) centered at the laser wavelength followed by a single mode fiber. The signal state was prepared in the conjugate mode when a SPCM (Perkin Elmer, SPCM-AQR-14-FC) registered the trigger photons. By temporally blocking the pump field, we estimated that ~2% of the trigger events occurred due to scattered laser light, corresponding to a preparation efficiency of ηp ~ 0.98. Trigger event rates up to 140 kHz were routinely observed.

A fraction of the original laser beam was split off before frequency doubling to provide the local oscillator (LO) for balanced homodyne detection. The local oscillator phase was allowed to vary randomly. The homodyne detector was aligned by coupling a 790 nm alignment beam into the trigger channel of parametric down-conversion. Classical difference frequency signal between the pump and alignment fields simulated the optical mode of the prepared signal photon [7,10], and was matched to the LO by optimizing the interference visibility therewith. By implementing a zoom lens configuration in the LO path, a visibility of ~ 85% was reached, corresponding to a mode-matching efficiency of ηm ~ 73% [7].

The homodyne detector circuit employed two Si-Pin photodiodes (Hamamatsu S5972) in a low-noise electronic subtraction circuit. These photodiodes possessed a quantum efficiency ηD = 85%, which is slightly lower than photodiodes typically used in high-speed homodyne detector circuitry in the past [8,11–14]. However, their lower capacitance and dark current permitted us to significantly improve the bandwidth and signal-to-noise characteristics. The difference photocurrent was processed by an operational amplifier (OPA 847) in the transimpedance gain configuration. The detector had a ~3 dB bandwidth at ~90 MHz, exceeding the repetition frequency of the LO pulses. The shot noise, measured at an average LO power of 25 mW, was ~14 dB higher than the electronic noise, corresponding to an electronic quantum efficiency of ηel ~ 93% [15].

The amplified difference photocurrent signal produced with the homodyne detector was digitized with an acquisition card (Agilent Acqiris DP211), integrated, and displayed in real time. With each trigger event, 128-ns data segments were acquired. In this way, quadrature measurements were collected for the signal pulse as well as 8 neighboring pulses, whose state was approximately vacuum, in order to calibrate the detector [15]. The acquisition rate, about 25,000 segments per second, was limited by the information transfer rate between the acquisition card and the computer. The acquired quadrature data corresponds to the state \( |\rho\rangle = (1 - \eta)|0\rangle|0\rangle + \eta|1\rangle|1\rangle \), where η is the overall quantum efficiency [6].

The variance of the acquired quadratures is then given by \( \langle Q^2 \rangle = \frac{1}{2} + \eta \) (using a scaling convention in which \( \langle Q^2 \rangle = \frac{1}{2} \) for the vacuum state). The value of η obtained from the variance was calculated and displayed periodically on acquisition of a specific number of data segments, typically 4000 to 6000 (corresponding to a display update rate of 4 to 5 times a second). The alignment of various parts of the setup could be improved using the displayed efficiency as a guide. Typically, starting from a preliminary alignment using classical fields, we were able to increase the efficiency by 5–10%.

Upon optimization of the setup, a large data set of 10^6 points was acquired and subjected to detailed analysis [Fig. 2(a,b)]. First, we corrected for residual correlations caused by a finite bandwidth of the homodyne detector, which lead to an additional quantum efficiency improvement of 0.5% on average. The maximum likelihood method [8,16,17] was then used to reconstruct the diagonal density matrix elements shown in the left column of Table 1 and in Fig. 2(c). Contributions of higher number states were negligible.

The vacuum state data yielded the density matrix elements displayed in the right column of Table 1 with negligible errors [Fig. 2(d)]. The presence of the two-photon component in the vacuum state estimation is due to the persistent non-Gaussian “hump” around \( Q = 0 \) in the marginal distribution [Fig. 2(b)] which we believe to
which we find $\eta_t \approx 7\%$, which is consistent with direct estimate of the trigger channel transmission.

In summary, we have reported homodyne reconstruction of the single-photon Fock state produced using conditional measurements on photon pairs generated via type-II spontaneous parametric down-conversion in a periodically poled KTP crystal with a detection rate on the scale of 100 kHz. The single-photon reconstruction fidelity is comparable to that reported previously [6,9,13]. The combination of the preparation rate as well as fast measurement and analysis permitted virtually instantaneous tomographic characterization, so optimization of the experimental setup in real time was possible. The achieved parameters of the experimental setup permit implementation of various new experiments in quantum-optical engineering and information processing that require simultaneous operation of two and three single-photon sources.
