Out-of-hours primary percutaneous coronary intervention for ST-elevation myocardial infarction is not associated with excess mortality: a study of 3347 patients treated in an integrated cardiac network

ABSTRACT

Objectives: Timely delivery of primary percutaneous coronary intervention (PPCI) is the treatment of choice for ST-segment elevation myocardial infarction (STEMI). Optimum delivery of PPCI requires an integrated network of hospitals, following a multidisciplinary, consultant-led, protocol-driven approach. We investigated whether such a strategy was effective in providing equally effective in-hospital and long-term outcomes for STEMI patients treated by PPCI within normal working hours compared with those treated out-of-hours (OOHs).

Design: Observational study.

Setting: Large PPCI centre in London.

Participants: 3347 STEMI patients were treated with PPCI between 2004 and 2012. The follow-up median was 3.3 years (IQR: 1.2–4.6 years).

Primary and secondary outcome measures: The primary endpoint was long-term major adverse cardiac events (MACE) with all-cause mortality a secondary endpoint.

Results: Of the 3347 STEMI patients, 1299 patients (38.8%) underwent PPCI during a weekday between 08:00 and 18:00 (routine-hours group) and 2048 (61.2%) underwent PPCI on a weekday between 18:00 and 08:00 or a weekend (OOHs group). There were no differences in baseline characteristics between the two groups with comparable door-to-balloon times (IHs 116.63 vs OOHs 127.15 min, p=0.709), call-to-balloon times (IHs 116.63 vs OOHs 127.15 min, p=0.60) and procedural success. In hospital mortality rates were comparable between the two groups (IHs 3.6% vs OOHs 3.2%) with timing of presentation not predictive of outcome (HR 1.25 (95% CI 0.74 to 2.11)). Over the follow-up period there were no significant differences in rates of mortality (IHs 7.4% vs OOHs 7.2%, p=0.442) or MACE (IHs 15.4% vs OOHs 14.1%, p=0.192) between the two groups. After adjustment for confounding variables using multivariate analysis, timing of presentation was not an independent predictor of mortality (HR 1.04 95% CI 0.78 to 1.39).

Conclusions: This large registry study demonstrates that the delivery of PPCI with a multidisciplinary, consultant-led, protocol-driven approach provides safe and effective treatment for patients regardless of the time of presentation.
Primary PCI for STEMI is not associated with excess out-of-hours mortality

ARTICLE SUMMARY

Strengths and limitations of this study
- The strength of this study is that it assesses outcome in a large contemporary cohort of consecutive patients undergoing PPCI for STEMI in a regional Heart Attack Centre, and therefore the results are likely to be widely generalisable. The large cohort also ensures that all-cause mortality can be used as the primary end point, which has the advantage of being entirely objective.
- This study is a consecutive but retrospective observational analysis from a single centre's experience. We cannot account for the effects of residual confounding factors or selection bias that we have been unable to control for.

BACKGROUND

There is increasing evidence suggesting that patients admitted during the weekend have a higher mortality than those admitted during the week. This excess mortality is thought to be strongly associated with the lack of cover of senior doctors (consultant level) during the weekends and has led to debate around redesigning healthcare provision to eliminate reduced staffing at the weekends.

Primary percutaneous coronary intervention (PPCI) is the accepted gold standard for the treatment of ST-segment elevation myocardial infarction (STEMI) as recognised in all recent guidelines, and needs to be available at all hours (24/7). The delivery of PPCI services represents a significant logistical challenge, especially as many patients with STEMI present outside of usual hospital working hours (0800–1700) and at weekends. Whether patients with STEMI presenting outside of usual hospital working hours have inferior outcomes when compared with patients who present during the working day is still unclear.

Previous studies have demonstrated differing results in outcome after PPCI during ‘in-hours’ (IHs) compared with ‘out-of-hours’ (OOHs). Some studies showed no association with adverse outcomes and timing whereas other studies suggested higher rates of mortality after PPCI during ‘out of hours’ compared with ‘in hours’. It is difficult to compare these studies directly because of differences in patient characteristics and variability in other treatment provided to patients—for example, some of these studies also used fibrinolysis.

The aim of this study was therefore to compare the relative outcomes of patients with STEMI presenting to a UK regional PPCI centre outside of usual hospital working hours with patients presenting during usual working hours.

METHODS

This was an observational cohort study of 3347 consecutive patients undergoing PPCI in a high volume centre between January 2004 and July 2012. These patients were divided into two groups based on the timing of PPCI (time taken as hospital arrival time). Those undergoing PPCI during usual hospital working hours, designated the ‘IH’ group (between 08:00 and 17:00 Monday to Friday), and those undergoing PPCI outside of usual hospital working hours, designated the ‘OOH’ group (ie, between 1701 and 0759 Monday to Friday and from 1701 Friday to 0759 Monday).

Service arrangement

The London Chest hospital is the tertiary heart attack centre for the North-East region of London and receives patients with STEMI for primary PCI in an unselected manner. This includes patients with cardiogenic shock and postcardiac arrest, including intubated and ventilated patients. The hospital serves a well-developed network of six local district general hospitals covering a population of 1.6 million people and includes close working with the London Ambulance Service. Patients are taken directly to the cardiac catheterisation laboratory 24 h a day with all cases performed by/under supervision of a consultant. OOHs, the catheterisation laboratory is covered by an ‘on-call team’. The on-call team is composed of an interventionalist cardiologist, a senior cath lab trainee, two cardiac catheterisation laboratory nurses, a cardiac physiologist and a radiographer. Aside from the senior cardiology trainee who is a resident in hospital OOHs, all the on-call team members are non-resident. OOHs, there are also reduced trainees covering the patients’ care postprocedure and other non-cardiac hospital services are also reduced with lower levels of staffing in radiology, pathology and anaesthesiology (ITU) (all these services follow a similar consultant lead service OOHs).

PPCI pathway

During OOHs periods, the on-call team members are contacted immediately upon acceptance of a patient for PPCI. The on-call team members will be in the hospital within 40 min of the original call and the catheterisation laboratory will be ready to take the patient as soon as they arrive. In the majority of cases, the on-call team will be in the hospital before the arrival of the patient. During routine working hours, the on-call team is in the hospital and the catheterisation laboratories are functioning fully. Upon accepting a patient, the catheterisation laboratory coordinators inform the on-call interventionalist cardiologist and cath lab trainee and the next available free catheterisation laboratory is identified. The patient is taken to the catheterisation laboratory and PPCI is performed by the interventionalist cardiologist who is working in that laboratory. Standard PPCI protocol for our institution includes preloading with 300 mg aspirin, 300 or 600 mg clopidogrel and GPIIb/IIIA inhibitors unless contraindicated. Aspiration thrombectomy was performed at the operator’s discretion.
Data were entered prospectively into the clinical database at the time of PPCI including patient characteristics, procedural factors and procedural complications. Successful primary PCI result was defined as final thrombolysis in myocardial infarction flow grade 3 and residual stenosis <30% in the infarct-related artery at the end of the procedure. Postdischarge complications and further revascularisation procedures were entered retrospectively from the electronic patient record and cardiac surgical database. Major Adverse Cardiac Events (MACE) were defined as death, recurrent myocardial infarction (defined as ‘new ischaemic pain with new ST elevation, or ischaemic ECG changes and a further elevation of enzymes (increase of creatine kinase-MB to ≥2 times the reference value or a rise in troponin T>30 ng/l (99th centile <10 ng/L)), whether treated with further revascularisation therapy or not’) and target vessel revascularisation. MACE events (identified from patient notes and electronic records) were adjudicated by three independent physicians who were not involved in the procedure and were unaware of the patient’s PPCI timing (IHs vs OOHs). All-cause mortality was recorded up to 11 September 2012 from the UK Office of National Statistics. A retrospective data quality audit of 100 randomly selected medical records established that 94.8% of data fields, including complications, were entered correctly into the database.

**Statistical analysis**

Continuous variables are presented as mean±SD and categorical variables as absolute number and percentages. Normality of distribution of continuous variables was assessed using the Shapiro-Wilkes test. Normally distributed continuous variables were compared with unpaired t tests, and non-normally distributed variables were compared with the Mann-Whitney test. Categorical variables

IHs, in-hours; OOHs, out-of-hours.
were compared using the χ² test or Fisher's exact test when appropriate. Kaplan-Meier curves were used to represent survival and cumulative incidence of events over follow-up, with the log rank test used for evidence of a statistically significant difference between the groups. Time was measured from the first admission for a procedure to outcome (all-cause mortality). The association of timing of PPCI (OOH vs IH) with 30-day mortality was assessed using logistic regression analysis, and long-term mortality using Cox regression analyses. The proportional hazard assumption was satisfied for all outcomes evaluated. Finally, a non-parsimonious logistic regression model with procedural timing as the dependent variable was constructed incorporating all baseline clinical and procedural characteristics listed in tables 1 and 2 to generate a propensity score (ie, the predicted probability of procedural timing for each patient), which ranged between 0 and 1 for each patient. We subdivided our cohort into quintiles based on propensity score so that comparisons could be made between patients with similar baseline probabilities of mortality. The rates of 30-day and 5-year mortality in the IH vs OOH groups in each quintile were compared. Risk ratios (RRs) for mortality were calculated for each quintile, as well as an overall Mantel-Haenszel RR for the stratified analysis.

RESULTS
Within our study population of 3347 patients, 1299 (38.8%) PPCIs were performed IHs and 2048 (61.2%) PPCIs were performed OOHs.

Patient characteristics
Table 1 demonstrates the baseline characteristics between the two groups. There were no differences in baseline characteristics between the IHs group versus the OOHs group.

Procedural characteristics and outcomes
There was no difference in access route or target vessel intervention between the two groups. Although the Door-to-Balloon time was slightly longer in the OOHs group compared with the IHs group, this difference was not statistically significant (figure 1). In addition, there was no statistically significant difference in the

|       | Multivessel disease | 1.92 (0.99 to 3.73) | 0.053   |
| MACE  | Age           | 1.02 (1.01 to 1.05) | <0.0001 |
|       | Shock         | 3.94 (2.30 to 6.74) | <0.0001 |
|       | eGFR>60       | 0.44 (0.28 to 0.69) | <0.0001 |
|       | EF>40         | 0.46 (0.30 to 0.71) | <0.0001 |
|       | Procedural success | 0.26 (0.15 to 0.46) | <0.0001 |
|       | Multivessel disease | 1.57 (1.31 to 1.90) | 0.003   |
|       | Out-of-hours  | 0.81 (0.54 to 1.22) | 0.316   |

EF, ejection fraction; eGFR, epidermal growth factor receptor; MACE, major adverse cardiac events.

Figure 1. Boxplots illustrating door-to-balloon times for primary percutaneous coronary intervention performed in-hours and out-of-hours. The median door-to-balloon time is indicated. The boundaries of the box plots refer to the 25th and 75th centiles, with the whisker bars representing the 5th and 95th centiles.
Call-to-Balloon time between the two groups. There were higher rates of glycoprotein IIb/IIIa inhibitor use in the OOHs group compared with the IHs group. Procedural success rates and use of thrombectomy were similar between the two groups (table 2).

**Early outcomes**
There were no differences in the in-hospital MACE rates (IH 4.5% vs OOH 5.0%; \( p=0.644 \)). There was no difference in either the 30-day MACE rates (IH 6.3% vs OOH 5.8%; \( p=0.580 \)) or the 30-day mortality rates (IH 4.4% vs OOH 4.0%; \( p=0.613 \)) between the groups (table 3).

**Predictors of early outcome**
In terms of early (30 day) all-cause mortality and MACE events, OOHs PPCI was not an independent predictor of mortality (HR 0.74 (95% CI 0.42 to 1.29)) and MACE events (HR 0.81 (95% CI 0.54 to 1.22)). However, as expected, reduced renal function, shock, low ejection fraction and procedural success were independent predictors of early outcome (table 4).

**Long-term outcome**
Patients were followed up for a median of 3 years (IQR 1.2–4.6 years). MACE event rates were not different between the groups at 1 year (IH 11.8% vs OOH 11.3%; \( p=0.757 \)) or 3 years (14.2% vs 13.2%; \( p=0.489 \)). Mortality rates at 1 year (IH 6.3% vs OOH 6.2%; \( p=0.934 \)) and 3 years (OOH 7.1% vs 7.3%; \( p=0.938 \)) were not different between the groups (figures 2–4).

**Predictors of long-term outcome**
Timing of PPCI (OOHs vs IHs) was not a univariate predictor of all-cause mortality (unadjusted HR 1.04 (95%
Primary PCI for STEMI is not associated with excess out-of-hours mortality

CI 0.78 to 1.39; figure 5). Incorporation of timing of PPCI into a multivariate Cox model did not change this (adjusted HR 1.03 (95% CI 0.70 to 1.50; figure 6). In addition, timing of PPCI was also not an independent predictor of MACE (unadjusted HR 0.93 (95% CI 0.76 to 1.14).

Stratification of risk by propensity score (long-term outcome)

Analysis of patients stratified into quintiles using propensity score showed that higher risk patients were less likely to undergo PPCI OOHs (68.2% in Q1 vs 57.8% in Q5; table 5). There was no significant difference in long-

DISCUSSION

We report both short-term and long-term outcomes after PPCI for STEMI in a contemporary cohort of patients presenting in and out of usual hospital working hours at a regional UK heart attack centre. We have found that the timing of presentation to hospital does not affect mortality after STEMI. Importantly, there was no difference in effective treatment delivery as evidenced by door-to-balloon and call-to-balloon times between patients presenting IHs and those presenting OOHs. That rapid reperfusion can be achieved despite reduced staffing levels is likely to be the key to the equivalent outcomes of our OOH population.

It was first recognised in the 1970s that throughout the Western world mortality is up to 10% higher in patients admitted to acute hospitals at the weekend than during the week, with cardiovascular disease being one of the main causes of this excess mortality. In particular, there has been a focus on studies that have suggested increased mortality (due to delayed care) in patients with severe medical conditions who are admitted during weekends. Kostis et al also found higher mortality in patients with myocardial infarctions admitted on weekends.

Interest in patient management and safety outside normal working hours has increased recently following a report by Dr Foster Intelligence that showed increased mortality in UK hospitals at the weekend, and suggested a clear association between this excess and the reduced numbers of senior doctors in hospitals. Our study clearly shows that the availability of a consultant-led, protocol-driven service at all times of day abolishes the excess mortality in UK hospitals. Our study clearly shows that the availability of a consultant-led, protocol-driven service at all times of day abolishes the excess OOHs risk for myocardial infarction—one of the main causes of in-hospital mortality.

Hospital staffing is often reduced OOHs compared with normal working hours, which has been linked to increased mortality. In our study, despite the reduced staffing levels and support services at weekends, there was no excess in adverse outcomes, suggesting that suitable seniority and experience of the medical care on site is a crucial rather than an exact replication of weekday service provision. The clear consultant-led protocol that we adopt at our high volume institution is key to providing a standardised management strategy for patients, whether it is ‘in hours’ or ‘out of hours’. In our opinion, this system could be adapted to other acute medical emergencies such as upper gastrointestinal bleeds, diabetic ketoacidosis and acute cerebrovascular accidents, although we appreciate that the impact of consultant-led protocol is likely to be different between procedure-based and non-procedure-based emergency therapies.

Providing a 24/7 service for PPCI is a challenge for both hospitals, medical personnel and the emergency medical services. Recent studies have found that up to two-third of STEMI patients are admitted to a PPCI centre outside normal working hours—this was also the case for our series. A finding in the Dr Foster report was that the creation of networks through rationalisation of services in parts of the UK may improve outcomes at weekends, a strategy appropriate for a population such as London. Our study shows that the creation of one such network for Primary PCI in the North East of London is safe and leads to improved outcomes. Similar strategies could be implemented for other acute medical conditions to improve outcomes ‘out of hours’ without involving complete replication of weekday hospital services at the weekend.

Strengths and limitations of the current study

Our study is a consecutive but retrospective observational analysis from a single centre’s experience. We cannot account for the effects of residual confounding or selection bias. The strength of this study is that it assesses outcome in a large contemporary cohort of consecutive patients undergoing PPCI for STEMI in a regional Heart Attack Centre. Therefore, the results are likely to be widely generalisable. The large cohort also ensures that all-cause mortality can be used as the primary end point. This has the advantage of being entirely objective. As this was an observational study, the findings may have been subject to confounding factors that we have been unable to control for. However, our dataset includes all major clinical variables known to affect outcome, which would support the validity of our results.
CONCLUSIONS
A consultant-led protocol for provision of PCI for treatment of STEMI is not associated with an increase in mortality for patients treated OOHs compared with IHs.
