Rydberg interaction induced enhanced excitation in thermal atomic vapor

Dushmanta Kara, Arup Bhowmick & Ashok K. Mohapatra

We present the experimental demonstration of interaction induced enhancement in Rydberg excitation or Rydberg anti-blockade in thermal atomic vapor. We have used optical heterodyne detection technique to measure Rydberg population due to two-photon excitation to the Rydberg state. The anti-blockade peak which doesn’t satisfy the two-photon resonant condition is observed along with the usual two-photon resonant peak which can’t be explained using the model with non-interacting three-level atomic system. A model involving two interacting atoms is formulated for thermal atomic vapor using the dressed states of three-level atomic system to explain the experimental observations. A non-linear dependence of vapor density is observed for the anti-blockade peak which also increases with increase in principal quantum number of the Rydberg state. A good agreement is found between the experimental observations and the proposed interacting model. Our result implies possible applications towards quantum logic gates using Rydberg anti-blockade in thermal atomic vapor.

Long range many body interaction in Rydberg atoms give rise to many interesting phenomena. The suppression in Rydberg population or the excitation blockade is the most striking one giving rise to a variety of applications. A highly dense atomic ensemble behaves like a single super atom producing a strongly correlated many body system and also leading to a single photon source. The phenomenon has been experimentally observed in an atomic ensemble in a magneto optical trap, in a magnetic trap and also in a single atom trap. Many theoretical models focus on the study of strongly correlated many body system in ultra cold atom and Bose Einstein condensate. Rydberg blockade interaction can induce optical non-linearity which is non-local and also strong enough to observe for single photon. Rydberg blockade interaction may also lead to applications such as quantum gates using atoms. An opposite effect of Rydberg blockade with enhancement in Rydberg excitation facilitated by interaction called as the Rydberg anti-blockade has been proposed in ultra cold atomic gas using a two photon excitation to Rydberg state. An experiment performed in ultra cold ensemble of atoms verifies the effect based on the theoretical model. It has been proposed that resonant dipole dipole interaction has non-additive character due to anti-blockade in an ensemble having more than two atoms in the blockade sphere. In addition to this, the existence of anti-blockade between two Rydberg atoms, interacting with a zero area phase jump pulse is also reported. Some recent results have also been reported to study Rydberg anti-blockade in atomic and molecular resonances. The implementation of quantum logic gate using Rydberg anti-blockade has also recently been proposed.

Recent experiments with thermal vapor have drawn the attention to study Rydberg interaction induced many-body effects. Electromagnetically induced transparency involving Rydberg state in thermal vapor cell as well as in micron size vapor cell has been studied. In addition, four wave mixing for a Rydberg state and kerr non-linearity in Rydberg EIT has also been reported in thermal Rubidium vapor. A recent study of Rydberg blockade in thermal atomic vapor has also been performed. Anomalous excitation facilitated by Rydberg interaction has also been proposed recently in thermal atomic vapor. In this article, we present a strong evidence of enhancement in Rydberg excitation due to interaction in thermal atomic vapor. An interacting twoatom model is formulated using the dressed state picture of a three level system in cold atomic ensemble. The model is further extended to thermal atomic vapor by Doppler averaging over the ensemble. An experiment has been performed in thermal rubidium vapor using optical heterodyne detection technique to observe the anti-blockade effect.

A good match is found between the model and the experimental observation as an evidence of the existence of enhancement in Rydberg excitation.
Rydberg anti-blockade in thermal atomic vapor. This is the first ever direct spectroscopic observation of Rydberg anti-blockade in thermal atomic vapor.

Results

Theoretical model. Let us consider a three level atomic system with states $|g\rangle$, $|e\rangle$ and $|r\rangle$ as shown in Fig. 1(a). The probe (coupling) laser drives the transition $|g\rangle\rightarrow|e\rangle$ ($|e\rangle\rightarrow|r\rangle$) with Rabi frequency $\Omega_p$ ($\Omega_c$) and detuning $\Delta_p$ ($\Delta_c$). Both of these transitions are dipole allowed whereas the transition $|g\rangle\rightarrow|r\rangle$ is dipole forbidden. The population decay rates of the transitions $|e\rangle\rightarrow|g\rangle$ and $|r\rangle\rightarrow|e\rangle$ are $\Gamma_{eg}$ and $\Gamma_{re}$ respectively. We have also included a decay rate $\Gamma_{gr}$ to account for the indirect decay of the state $|r\rangle\rightarrow|g\rangle$ due to finite transit time of the thermal atoms. In the regime $\Omega_c \ll \Omega_p$, interaction with the coupling laser can be treated as a small perturbation to the atomic states dressed by the strong probe laser. For large probe detuning $\Delta_p \gg \Omega_p$ and $\Gamma_{eg}$, the dressed states are given by $|g_1\rangle \approx |e\rangle + \frac{\Omega_p}{2\Delta_p} |g\rangle$ and $|g_2\rangle \approx |g\rangle - \frac{\Omega_p}{2\Delta_p} |e\rangle$ with difference in their energy eigenvalues $\Delta \approx \Omega_p + \frac{\Delta_p^2}{2}\Omega_p$. The steady state population of the dressed states can be determined by diagonalizing the steady state density matrix for the two-level atomic transition $|g\rangle\rightarrow|e\rangle$ driven by the strong probe laser. The population of the states $|g_1\rangle$ and $|g_2\rangle$ are found to be approximately $\Omega_p^2/16\Delta_p^2$ and 1 respectively. When the coupling laser is scanned over these dressed states, each of them will behave like a ground state exciting to the Rydberg state by the coupling laser. It is to be noted that the optical pumping rate to achieve the steady state population of the dressed states is $\Gamma_{eg}$. If $\Omega_c \ll \Gamma_{eg}$ then the coupling laser driving to the Rydberg state can not build the coherence between the dressed states. Hence, both the states can be treated independently and the total Rydberg population can be determined by adding the individual Rydberg populations driven from each of the dressed states. The coupling Rabi frequencies are scaled for each dressed state as $\Omega_1 \approx \Omega_c$ for the transition $|g_1\rangle\rightarrow|r\rangle$ and $\Omega_2 \approx \Omega_p\Omega_c/2\Delta_p$ for the transition $|g_2\rangle\rightarrow|r\rangle$. Similarly, the population of the Rydberg state will decay to the states $|g_1\rangle$ and $|g_2\rangle$ with decay rates as $\Gamma_1 \approx \Gamma_{eg} + \frac{\Omega_p}{2\Delta_p} \Gamma_{re}$ and $\Gamma_2 \approx \Gamma_{eg} + \frac{\Omega_p}{2\Delta_p} \Gamma_{re}$ respectively.

Considering two atoms driven to the Rydberg state simultaneously, there are four possible dressed states as $|g_1g_1\rangle$, $|g_1g_2\rangle$, $|g_2g_1\rangle$ and $|g_2g_2\rangle$. The states $|g_1g_1\rangle$ and $|g_2g_2\rangle$ are degenerate and have equal steady state population of $\Omega_p^2/16\Delta_p^2$. The population of the state $|g_1g_2\rangle$ is approximately 1 and that of $|g_2g_1\rangle$ is negligibly small for $\Omega_p \ll \Delta_p$. The difference in the energy eigenvalues of $|g_1g_2\rangle$ and $|g_2g_1\rangle$ is $\Delta$ which can be made larger than the typical Doppler linewidth of the transition in thermal vapor. If a narrow band laser is made resonant to the transition $|g_1g_2\rangle\rightarrow|r\rangle$, then the laser will be out of resonance to drive the atoms in the state $|g_2g_1\rangle$ to the

![Figure 1. The relevant energy level diagrams. (a) A probe laser driving the $|g\rangle\rightarrow|e\rangle$ transition of a single atom leads to the dressed states $|g_1\rangle$ and $|g_2\rangle$. The coupling laser drives the dressed states to the Rydberg state $|r\rangle$ with detuning $\Delta_p \approx \Delta_c - \Omega_p^2/4\Delta_p$ and $\Delta_2 \approx \Delta_p + \Omega_p^2/4\Delta_p$ respectively. (b) The two atom model with states $|g_1g_2\rangle$ representing an atom in each dressed state, $|g_1r\rangle$, $|rg_2\rangle$ representing one atom in the respective dressed state and other atom in the Rydberg state and $|rr\rangle$ representing both the atoms in the Rydberg state.](image-url)
Rydberg state. In the regime $\Omega_c \ll \Gamma_{eg}$, the coupling laser can't introduce coherence between the states $|g_1g_2\rangle$ and $|g_2g_1\rangle$. Hence, either of the states can be considered in the two atom model to determine the Rydberg population with proper normalization accounting for both the states. Thus in the simplified model, only one of the dressed states of the two atomic system can be considered to model the anti-blockade peak. As shown in Fig. 1(b), the relevant energy level diagram to model the anti-blockade peak are $|g_1r_1\rangle$, $|g_2r_2\rangle$, $|rg_1\rangle$ and $|rr\rangle$. Steady state solutions of the master equation using the above simplified model and averaging over the thermal ensemble (see method section) is depicted in Fig. 2. In the regime $\Omega_c \ll \Gamma_{eg}$, the non-interacting two-atom dressed state model matches excellent with the exact three-level single atom calculation which tends to deviate with increase in $\Omega_c$ above $\Gamma_{eg}$. It can be shown that the $|g_1\rangle \rightarrow |r\rangle$ transition is equivalent to the effective two-level transition ($|g_1\rangle \rightarrow |r\rangle$) by adiabatically eliminating the intermediate state $|e\rangle$ of a three-level system.

The Rydberg population due to the $|g_1\rangle \rightarrow |r\rangle$ transition which is neglected in the model with effective two-level system can be shown to be enhanced due to Rydberg-Rydberg interaction. Hence, the exact model for three-level system for two interacting atoms is necessary to study the anti-blockade peak. However, for the given laser parameters discussed above, the dressed state model is simplified due to reduced Hilbert space relevant for modelling the anti-blockade peak.

Rydberg-Rydberg interaction can easily be introduced in the model by including the shift in energy of the $|rr\rangle$ state. Rydberg anti-blockade in thermal vapor is illustrated in Fig. 3. Consider a case where the narrow band laser is resonant to the $|g_1g_2\rangle \rightarrow |rg_1\rangle$ transition as depicted in Fig. 3(a). Then the atom in the dressed state $|g_1\rangle$ is excited to the Rydberg state. The same laser will be out of resonance to the $|g_2g_1\rangle \rightarrow |g_2r\rangle$ transition. If the Rydberg-Rydberg interaction is absent then the state $|rr\rangle$ will also not satisfy the resonant condition. Therefore, the second atom in the dressed state $|g_2\rangle$ can't be excited to the Rydberg state. Suppose the interaction shift of the $|rr\rangle$ state is equal to $\Delta'$ (difference in the resonant frequencies corresponding to the $|g_1g_2\rangle \rightarrow |rg_1\rangle$ and $|g_2g_1\rangle \rightarrow |g_2r\rangle$ transitions) then the $|rr\rangle$ state will be resonant to the laser as shown in Fig. 3(a). Now the second atom present in the state $|g_2\rangle$ will also be excited to the Rydberg state unlike a non-interacting system. So the presence of the Rydberg interaction facilitate the excitation of the second atom enhancing the total Rydberg population compared to the non-interacting case and this phenomenon is known as Rydberg anti-blockade. Rydberg anti-blockade peak appears when the coupling laser is resonant to the $|g_1\rangle \rightarrow |r\rangle$ transition i.e. near $\Delta_c = 0$, whereas the usual two-photon resonant peak appears with the coupling laser resonating to the $|g_2\rangle \rightarrow |r\rangle$ transition. Referring to Fig. 3(b), consider an interaction sphere with radius $r_j$ where $r_j$ is defined as the blockade radius and is given by $r_j = \frac{C_r}{\sqrt{\text{an}}}$, with $C_r$ being the coefficient of van der Waals interaction. Consider the atom in the dressed state $|g_2\rangle$ resonating to the coupling laser to be at the center of the sphere. Assume that the second atom in the dressed state $|g_1\rangle$ is present in a concentric spherical shell with radius $|r|$. Figure 3(b) shows the Rydberg population as a function of coupling laser detuning. Rydberg population calculated using exact three level single atomic system and two-atoms non-interacting model are represented by the solid line and the symbol (*) respectively. Inset shows the magnified view of the peak near $\Delta_c = 0$. Laser parameters used in the calculation are $\Omega_p = 400$ MHz, $\Omega_c = 5$ MHz and $\Delta_p = 1.25$ GHz.

Figure 2. Rydberg population as a function of coupling laser detuning. Rydberg population calculated using exact three level single atomic system and two-atoms non-interacting model are represented by the solid line and the symbol (*) respectively. Inset shows the magnified view of the peak near $\Delta_c = 0$. Laser parameters used in the calculation are $\Omega_p = 400$ MHz, $\Omega_c = 5$ MHz and $\Delta_p = 1.25$ GHz.
depicted in the same figure. Anti-blockade peak is observed to be enhanced significantly due to interaction compared to the non-interacting case. Referring to eq. (1) in method section, the dispersion of the probe beam due to two atoms interaction depends strongly on the principal quantum number of the Rydberg state and also depends quadratically on the density of the atomic vapor. The dispersion peak height of the anti-blockade peak calculated from the interacting model showing a quadratic dependence on the density of the atomic vapor is depicted in Fig. 3(d).

**Experimental results and discussions.** Schematic of the experimental set up is depicted in Fig. 4(a). Optical heterodyne detection technique (OHDT)\(^{42,45}\) was used to measure the dispersion of the probe beam propagating through a magnetically shielded rubidium vapor cell. The details of the OHDT and the theoretical model for relating the dispersion with Rydberg population can be found in ref.\(^{45}\). Optical heterodyne detection technique requires a probe laser beam along with a reference laser beam which were derived from an external cavity diode laser operating at 780 nm. A frequency offset of 800 MHz between the probe and the reference beams was introduced using acousto-optic modulators. The coupling laser beam operating in the range of 478 nm to 482 nm counter-propagates the probe beam through the vapor cell. The overlapping between the probe and coupling beam was ensured by optimizing the Rydberg EIT signal. The beam waist of the probe (coupling) laser was 95 μm (80 μm) and the respective Rayleigh range was 36.33 mm (41.86 mm). The probe laser power was kept fixed at 4 mW throughout the experiment. For the coupling laser the power was varied following the \(n^{3/2}\) law, so as to keep the coupling rabi frequency constant for all the \(n\) states. The Rabi frequencies of the probe and coupling beams were determined from their intensity using the method discussed in ref\(^{42}\). The inhomogeneity of the laser intensity profile is neglected in the model and the averaged Rabi frequencies were used to compare with the experimental observation. The density of the vapor was varied by heating the cell and the temperature was controlled using a PID controller. The non-linear phase shift of the probe laser due to two-photon excitation to the Rydberg state in the presence of the coupling laser can be measured by comparing the phase of the reference beam using OHDT\(^{45}\). A typical dispersion spectrum observed in the experiment is shown in Fig. 4(b).
The experiment was performed for the Rydberg states $35S_{1/2}$, $40S_{1/2}$, $45S_{1/2}$ and $53S_{1/2}$. The dispersion of the probe beam was measured using OHDT by varying the density of the rubidium vapor with laser parameters $\Omega_P = 400$ MHz, $\Omega_C = 4$ MHz and $\Delta_P = 1.25$ GHz. All the laser parameters including the gain in the set up were kept fixed throughout the experiment for all the Rydberg states. As predicted in the theoretical model, two different peaks were observed for the dispersion spectrum of the probe beam when the coupling laser is scanned over few GHz. One of them is the usual two photon resonant peak and the other one is the anti-blockade peak. Since the Rydberg-Rydberg interaction is repulsive, the anti-blockade peak is expected to be observed on the blue detuned side of the dispersion spectrum. For lower principal quantum number states the Rydberg interactions is weak and is significant only at very high atomic density. However, with increase in the principal quantum number states the Rydberg interactions is strong and is significant at lower atomic density as well.

Figure 4. (a) Schematic of the experimental set up. (b) A typical dispersion spectrum of the probe laser observed using the optical heterodyne detection technique showing the resonant peaks corresponding to $5S_{1/2}F = 3 \rightarrow nS_{1/2}$ and $5S_{1/2}F = 2 \rightarrow nS_{1/2}$ of $^{85}$Rb.

Figure 5. Dispersion spectrum measured from the experiment (black triangle) and calculated from the interacting two-atom model (open circle) for the Rydberg state with principal quantum numbers (a) $n = 35$ (b) $n = 40$ (c) $n = 45$ and (d) $n = 53$. For comparison, dispersion calculated from the non-interacting model is depicted as solid lines for all the $n$ states.
We have observed the interaction induced enhancement in Rydberg excitation in thermal rubidium vapor. A two atom interacting model is formulated using the dressed state picture of the three level atomic system to explain the anti-blockade peak. The population of the Rydberg state is observed to be enhancing quadratically as the applied laser is highly detuned from the atomic resonance resulting in linear dependence of density. For the two photon resonant peak, the anti-blockade effect is significantly larger on the blue detuned side compared to the red detuned side while coupling to the non-interacting model. The deviation on the blue detuned side of the spectrum is an indication of the dominating anti-blockade effect.

For a fixed atomic density, the height of the anti-blockade peak increases with the principal quantum number of the Rydberg state. The $C_n$ scaling with the principal quantum number could not be determined from the anti-blockade peak observed in the experiment. When the number of atoms in the $|g\rangle$ state in the interaction sphere is more than one, the blockade effect will contribute along with the cascaded processes involving more number of atoms. For a Rydberg state with $n = 35$, the interaction is small and the number of atoms in the $|g\rangle$ state in the interaction sphere, $N_b \approx 1$ at a density of $3.0 \times 10^{13}/\text{cc}$. Thus, the experimental data is expected to match well with the model. We measured the dispersion peak height for the anti-blockade peak and the two photon resonant peaks corresponding to the transitions $^{85}\text{Rb} \, S_{1/2} \, F = 2 \rightarrow 3S_{1/2}$ and $^{85}\text{Rb} \, S_{1/2} \, F = 3 \rightarrow 3S_{1/2}$ by varying the density of the vapor cell which is shown in Fig. 6. For $3S_{1/2}$, the anti-blockade peak height increases quadratically with increase in density as predicted in the model. For the other two peaks, the variation is observed to be linear. The peak corresponding to the transition $^{85}\text{Rb} \, S_{1/2} \, F = 2 \rightarrow 3S_{1/2}$ is expected to be non-interacting as the applied laser is highly detuned from the atomic resonance resulting in linear dependence of density. For the two photon resonant peak corresponding to $^{85}\text{Rb} \, S_{1/2} \, F = 3 \rightarrow 3S_{1/2}$, both the blockade and anti-blockade effects are present which may be compensating each other such that the variation with density is roughly linear. The dotted and dashed lines are the linear fittings and the solid line is the quadratic fit of the peak height data as shown in Fig. 6.

Conclusion
We have observed the interaction induced enhancement in Rydberg excitation in thermal rubidium vapor. A two atom interacting model is formulated using the dressed state picture of the three level atomic system to explain the anti-blockade peak. The population of the Rydberg state is observed to be enhancing quadratically with the density of the vapor for Rydberg state with $n = 35$, as predicted in the theoretical model. The experiment performed here is limited by the uncertainty in the density measurement. The density dependence of the anti-blockade peak can be studied with a better measurement of density and larger number of data. The deviation from the quadratic behavior can be measured to study the effect of blockade and the cascaded processes on the anti-blockade peak having more than one atom in the $|g\rangle$ state in the interaction sphere.

Methods
Non-interacting dressed state model. The Hamiltonian for driving two atoms together is given by $H = H^{(1)} \otimes 1 + 1 \otimes H^{(2)}$, where $H^{(1)} = \frac{\hbar}{2} (\Delta_1|g\rangle\langle g| + \Delta_1|f\rangle\langle f| + \Omega_1|g\rangle\langle f| + H.C.)$ and $H^{(2)} = \frac{\hbar}{2} (\Delta_2|g\rangle\langle g| + \Omega_2|g\rangle\langle g| + H.C.)$ are the Hamiltonian for the individual atoms. The Lindblad operator for the two-
Interacting dressed state model. Referring to Fig. 3, consider that the atom in the dressed state $|g_i\rangle$ is placed at the center of the interaction sphere and the other atom in the dressed state $|g_j\rangle$ is present in a concentric spherical shell with radius $r$ and thickness $dr$. Resonance condition to the $|rr\rangle$ state constrain the velocity of the second atom to depend on the velocity of first atom as well as on their inter-particle separation $s$. If the resonant atoms within the linear width of Rabi coupling are assumed to contribute significantly to the anti-blockade then the above constraint can be used to reduce the complexity of the model. Taking the vapor density as $n$, the number of atoms in the dressed state $|g_j\rangle$ present inside the spherical shell with radius $r$ is $n\pi r^2 dr$. Suppose, only the velocity class of atoms at $v_2$ within a small velocity width $\Delta v_2$ is $\Omega_2/\Delta k$ inside the same spherical shell satisfy the resonant condition to the $|rr\rangle$ state, then the effective number of atoms inside the interaction sphere contributing to the anti-blockade can be evaluated as $N_r(v_2) = \frac{\eta \pi r^2 \Delta k}{\Omega_2^2} \int_0^{\Delta v_2} e^{-\frac{v_2^2}{2\Delta_k^2}} dv_2$, where $v_2$ depends on $v_1$ and $r$. In the case of probe laser detuning larger than the Doppler width, $\Delta_0 \gg k_P v_2$, the light shift of the $|g_i\rangle$ state can be expanded to be $(1 + k_P v_2/\Delta_0)\Omega_2^2/4\Delta_0$, neglecting the higher order terms. Then, the velocity of the second atom is found to be $v_2 = (2\Delta_0^2 - \Delta_1(v_1)/\Delta_k)^k_2$, where $\Delta_1(v_1) = \Delta_0 + 2\Delta_0 + k_0 v_1 - k_0^2/4\Delta_0$ and $\Delta_k = k_0 + k_0^2/4\Delta_0$. The above integral can be calculated analytically to find the total number of atoms contributing to the anti-blockade as $N_r(v_2) = \frac{\eta \pi r^2 \Delta k}{\Omega_2^2}\frac{1}{\Delta_1(v_1)^k_2}$.

Rydberg population can be related to the dispersion which is a measurable quantity using optical heterodyne detection technique as $\Re[\chi_{34}(v_1)] = \frac{\eta}{\varepsilon_0}\frac{N_r(v_2)}{\varepsilon_0|\Delta_0|\Delta_1(v_1)}$. Averaging over the velocity distribution of the first atom, the dispersion of the probe due to anti-blockade can be evaluated as

$$\Re[\chi_{34}] = \frac{\Omega_2^2 \pi r^2 \frac{\Delta k}{\Delta_k}}{\varepsilon_0|\Delta_0|\Delta_k} \int_{-\infty}^{\infty} \frac{\rho_r(v_1) e^{(-v_1^2/2\Delta_k^2)}}{(\Delta_0 - k_0 v_1)(\Delta_1(v_1))^k_2} dv_1.$$

Acknowledgements
We would like to thank Dr. V. Ravi Chandra and Dr. Anamitra Mukherjee for their valuable suggestion for the theoretical modeling. We would like to thank Sushree S. Sahoo, Snigdha S. Pati and Tanim Firdoshi for assisting in performing the experiment. This experiment is financially supported by Department of Atomic Energy, Government of India.

Author Contributions
A.K.M. conceived the concept of anti-blockade in thermal vapor. A.K.M. and D.K. contributed to the theoretical modeling. D.K., A.B. and A.K.M. contributed in performing the experiment. D.K. analyzed the experimental data. All authors have contributed to the manuscript preparation.
