An alternative extended linear system for boundary value problems on locally perturbed geometries

Y. Zhang and A. Gillman

Abstract

This manuscript presents a new extended linear system for integral equation based techniques for solving boundary value problems on locally perturbed geometries. The new extended system is similar to the one presented by Greengard et al. (2009) [4] for which a fast direct solver was constructed by Zhang and Gillman (2018) [9] but the corresponding fast direct solver is more efficient than the one for the original extended system. Another important feature of the new extended system is that it can easily handle problems that require specialized quadrature for weakly singular kernels. Numerical results illustrate the improved performance of the fast direct solver for the new extended system when compared to the fast direct solver for the original extended system.

1 Introduction

This manuscript presents an integral equation based solution technique for elliptic boundary value problems on locally-perturbed geometries. Such problems arise in applications such as optimal shape design. In each iteration or optimization cycle the changes to the object shape often stay local to certain parts of the object. The proposed approach formulates an extended linear system that allows for the boundary value problem on the new geometry to be expressed in terms of a linear system on the original geometry plus a correction to account for the local perturbation. This idea was first proposed in [4] and a fast direct solver was constructed for the resulting formulation in [9]. Unfortunately, the fast direct solver for the original extended system required inverting a matrix the size of the number of points removed from the original geometry which is expensive if the removed portion is large. Another difficulty of the original extended system is that care is required when the technique is applied to systems discretized using quadrature for weakly singular kernels. The extended linear system proposed in this manuscript overcomes these two difficulties. Additionally, a fast direct solver for the new extended system can be constructed from the tools presented in [9] but is more efficient than the original fast direct solver.

This manuscript briefly reviews a boundary integral formulation for a Laplace problem with Dirichlet boundary data and the linear system that results from the discretization in section 2. Next, the original extended system and the new extended system are presented in section 3. Finally numerical results illustrate the efficiency of the fast direct solver for the new extended system in section 4.

2 Boundary integral formulation

Consider the interior Laplace problem with Dirichlet boundary condition

\[-\Delta u(x) = 0 \quad \text{for } x \in \Omega,\]
\[u(x) = g(x) \quad \text{for } x \in \Gamma\]  \hspace{1cm} (1)

where \(\Omega\) denotes the interior of the geometry, and \(\Gamma\) denotes the boundary of \(\Omega\), as illustrated in Figure 1(a). Let \(G(x, y) = -\frac{1}{2\pi} \log |x - y|\) denote the Green’s function for the Laplace operator and \(D(x, y) = \)
\( \partial_n(y)G(x, y) \) denote the double layer kernel where \( n(x) \) denotes the outward facing normal vector at the point \( x \in \Gamma \). The solution to \( (\mathbf{1}) \) can be expressed as

\[
u(x) = \int_{\Gamma} D(x, y)\sigma(y)ds(y) \quad \text{for } x \in \Omega,
\]

where \( \sigma(x) \) is some unknown density defined only on the boundary \( \Gamma \). Enforcing that \( u(x) \) satisfies the boundary condition results in the following integral equation for \( \sigma(x) \);

\[
-\frac{1}{2}\sigma(x) + \int_{\Gamma} D(x, y)\sigma(y)ds(y) = g(x).
\]

Upon discretization via a Nyström or boundary element method, one is left with solving a dense linear system

\[
A\sigma = g,
\]

where \( A \) is the discretized boundary integral operator and \( \sigma \) is the vector approximating \( \sigma \) at the discretization points.

Figure 1: (a) A sample geometry \( \Omega \) with boundary \( \Gamma \) and outward facing normal vector \( n(x) \) at the point \( x \in \Gamma \). (b) A sample locally perturbed geometry where the original boundary is \( \Gamma = \Gamma_k \cup \Gamma_c \), the portion of the boundary being removed is \( \Gamma_c \), the portion of the original boundary remaining is \( \Gamma_k \) and the newly added boundary is \( \Gamma_p \).

3 Extended linear systems

Consider a boundary value problem on a geometry with a local perturbation as illustrated in Figure 1(b). Let \( \Gamma_o \) denote the boundary of the original geometry, \( \Gamma_k \) denote the portion of the boundary that is not changing and \( \Gamma_c \) denote the portion that is cut or removed. So \( \Gamma = \Gamma_o \cup \Gamma_k \). Let \( \Gamma_p \) denote the new portion of the boundary. Then the new geometry has a boundary \( \Gamma_n \) defined by \( \Gamma_n = \Gamma_k \cup \Gamma_p \).

The discretized linear systems can be partitioned according to this notation. In other words, the original system can be expressed as

\[
A_{oo}\sigma_o = \begin{bmatrix} A_{kk} & A_{kc} \\ A_{ck} & A_{cc} \end{bmatrix} \begin{bmatrix} \sigma_k \\ \sigma_c \end{bmatrix} = \begin{bmatrix} g_k \\ g_c \end{bmatrix} = g_o,
\]

and the linear system for the perturbed geometry can be expressed as

\[
A_{nn}\sigma_n = \begin{bmatrix} A_{kk} & A_{kp} \\ A_{pk} & A_{pp} \end{bmatrix} \begin{bmatrix} \sigma_k \\ \sigma_p \end{bmatrix} = \begin{bmatrix} g_k \\ g_p \end{bmatrix} = g_n
\]

where \( \sigma_k \) denotes the vector whose entries are the approximate solution at the discretization points on \( \Gamma_k \), \( \sigma_c \) denotes the vector whose entries are the approximate solution at the discretization points on \( \Gamma_c \), etc. Likewise \( A_{kk} \) is the submatrix of the discretized integral equation corresponding to the interaction of \( \Gamma_k \) with itself, \( A_{kc} \) is the submatrix of the discretized integral equation corresponding to the interaction of \( \Gamma_k \) with \( \Gamma_c \), etc.
3.1 Original extended linear system

The discretized problem on \( \Gamma_n \) can be expressed as an extended linear system \([4]\) by

\[
\begin{bmatrix}
A_{oo} & 0 \\
0 & A_{pp}
\end{bmatrix} + \begin{bmatrix}
0 & (-A_{kc}) \\
-A_{kc} & A_{op}
\end{bmatrix} Q_{orig} = \begin{bmatrix}
\sigma_k \\
\sigma_c
\end{bmatrix}
\begin{bmatrix}
\sigma_k \\
\sigma_c
\end{bmatrix} = \begin{bmatrix}
g_k \\
g_p
\end{bmatrix}
\]

(7)

where \( A_{kc} \) denotes the submatrix of \( A_{oo} \) corresponding to the interaction between \( \Gamma_k \) and \( \Gamma_c \), \( A_{op} \) denotes the discretization of the double layer integral operator on \( \Gamma_p \) evaluated on \( \Gamma_o \), \( A_{pk} \) denotes the discretization of the double layer integral operator on \( \Gamma_k \) evaluated on \( \Gamma_p \), and \( B_{cc} \) denotes the sub-matrix of \( A_{oo} \) corresponding to the interaction of \( \Gamma_c \) with itself but the diagonal entries are set to zero. The matrix \( Q_{orig} \) is called the update matrix. The extended system (7) is obtained by subtracting the contributions from \( \Gamma_c \) in \( A_{oo} \) and adding the contributions from \( \Gamma_p \). Upon solving (7), only \( \sigma_k \) and \( \sigma_p \) are used to evaluate the solution inside of \( \Gamma_n \). Effectively \( \sigma_c \) is a dummy vector. Details of the derivation of (7) are provided in [4, 9].

3.2 New extended linear system

We exploit the fact that the contribution from \( \Gamma_c \) is not used to find the solution inside of \( \Gamma_n \) in the new extended linear system. Specifically, we introduce the vector \( \sigma_c^{dum} \) fully knowing a priori that it will contain useless information. Then solving (6) is equivalent to solving the following

\[
\begin{bmatrix}
A_{kk} & 0 & A_{kp} \\
A_{ck} & A_{cc} & 0 \\
A_{pk} & 0 & A_{pp}
\end{bmatrix} \begin{bmatrix}
\sigma_k \\
\sigma_c^{dum} \\
\sigma_p
\end{bmatrix} = \begin{bmatrix}
g_k \\
0 \\
g_p
\end{bmatrix}
\]

(8)

The expanded form of (8) is

\[
\begin{bmatrix}
A_{oo} & 0 \\
0 & A_{pp}
\end{bmatrix} + \begin{bmatrix}
0 & -A_{kc} & A_{kp} \\
0 & 0 & 0 \\
A_{pk} & 0 & 0
\end{bmatrix} Q_{new} = \begin{bmatrix}
\sigma_k \\
\sigma_c^{dum} \\
\sigma_p
\end{bmatrix}
\begin{bmatrix}
\sigma_k \\
\sigma_c^{dum} \\
\sigma_p
\end{bmatrix} = \begin{bmatrix}
g_k \\
0 \\
g_p
\end{bmatrix}
\]

(9)

Here \( Q_{new} \) is the new update matrix. Notice that \( Q_{new} \) has a zero row.

3.3 A fast direct solver

When constructing the fast direct solver for the locally perturbed boundary value problem, there are advantages to writing the system in the form of (7) and (9). Since the matrix \( A_{oo} \) is the system resulting from the discretization of the integral equation on the original geometry, we assume that a fast direct solver was already computed for it. Any fast direct solver such as Hierarchically Block Separable (HBS) [3], Hierarchically Semi-Separable (HSS) [8, 1], Hierarchical Interpolative Factorization (HIF) [6] and \( \mathcal{H} \) and \( \mathcal{H}^2 \)-matrix methods [5] can be used. Additionally, the update matrices \( Q_{orig} \) and \( Q_{new} \) are low rank. This allows for the inverse of the extended systems to be applied rapidly via a Sherman-Morrison-Woodbury formula

\[
\sigma_{ext} = (A + Q)^{-1} g_{ext} \approx (A + LR)^{-1} g_{ext} \approx A^{-1} g_{ext} - A^{-1} L (I + RA^{-1} L)^{-1} RA^{-1} g_{ext},
\]

(10)
where $I$ is an identity matrix, and $LR$ denotes the low rank factorization of the update matrix $Q$.

The low rank property of the update matrices $Q_{\text{orig}}$ and $Q_{\text{new}}$ can be observed by noting that the matrices $A_{kc}$, $A_{kp}$, $A_{pk}$ and $A_{op}$ are low rank. The only full rank matrix in the update matrices is $B_{cc}$. Since $Q_{\text{new}}$ does not contain that matrix, its rank is smaller than $Q_{\text{orig}}$ and the Sherman-Morrison-Woodbury formula can be applied more rapidly. The details for efficiently creating the low rank factorizations can be found in [9].

## 4 Numerical experiments

This section illustrates the performance of the fast direct solver for the proposed extended linear system for a collection of problems. The integral equations are discretized via the Nyström method with a $16^{th}$ order composite Gaussian quadrature. For all problems, the original geometry is discretized with enough points in order for the boundary value problem to be solved to 10 digits of accuracy. The HBS direct solver [3] was used in the examples in this section. For all tests, the tolerance for HBS compression and low-rank approximation is set to $\epsilon = 10^{-10}$.

Roughly speaking the cost of building fast direct solvers is split into two parts: precomputation and solve. The time for precomputation is the time for constructing all the parts of the fast direct solver. For the extended systems, this includes constructing the low rank factorizations of the update matrices $Q_{\text{orig}}$ or $Q_{\text{new}}$ and inverting the small matrix in the Sherman-Morrison-Woodbury formula [10]. For the HBS solver, the precomputation includes creating a compressed approximation of the discretized system on the new geometry and inverting that approximation. The time for the solve is the time for applying the resulting solver to one vector (or right-hand-side). For the extended systems, this is the time for applying the Sherman-Morrison-Woodbury formula [10]. For the HBS solver, it is the time for applying the approximate inverse.

To illustrate the efficiency of the proposed technique, we compare the performance of the new solution technique with the fast solver developed for the original extended system and building an HBS solver from scratch for the new geometry. We report the following:

- $N_o$: the number of discretization points on the original geometry;
- $N_c$: the number of discretization points cut from the original geometry;
- $N_p$: the number of discretization points added;
- $T_{\text{new},p}$: the time in seconds for the precomputation of the proposed solver;
- $T_{\text{orig},p}$: the time in seconds for the precomputation of the original fast solver;
- $T_{\text{hbs},p}$: the time in seconds for the precomputation of HBS from scratch for the new geometry;
- $r_p = \frac{T_{\text{hbs},p}}{T_{\text{new},p}}$;
- $T_{\text{new},s}$: the time in seconds for applying the proposed solver to one right-hand-side;
- $T_{\text{orig},s}$: the time in seconds for applying the original solver to one right-hand-side;
- $T_{\text{hbs},s}$: the time in seconds for applying the HBS inverse to one right-hand-side;
- $r_s = \frac{T_{\text{hbs},s}}{T_{\text{new},s}}$.

The ratios $r_p$ and $r_s$ are measures for the speed-up (or slow-down) by using the proposed solver versus building a new fast direct solver from scratch for the new geometry. If $r_p$ is greater than 1, the precomputation of the proposed solver is faster than building a fast direct solver from scratch. If $r_p$ is less than 1, the precomputation of the proposed solver is slower than building a fast direct solver from scratch, etc.
All experiments were run on a dual 2.3 GHz Intel Xeon Processor E5-2695 v3 desktop workstation with 256 GB of RAM. The code is implemented in MATLAB, apart from the randomized linear algebra utilized in creating low rank factorization rapidly which is implemented in Fortran.

4.1 A local change in the geometry

Consider the Laplace boundary value problem (1) on the geometry illustrated in Figure 2. The corners are smoothed via the scheme in [2]. A detailed description of this geometry is given in [9].

In the first experiment, the number of points cut remains fixed, $N_c = 16$, while the number of discretization points on $\Gamma_k$ grows. In Figure 2 this corresponds to the nose height $d$ decreasing as $N_k$ grows. The results are reported in Table 1. All three solution techniques are linear with respect to $N_o$ and the precomputation time for the new solution technique is about the same as the original extended system solver. It is roughly 3.5 times faster than building a new direct solver from scratch for the new geometry. The cost of applying the proposed solver is almost as fast applying the HBS approximate inverse.

In the next example, $N_c$ grows by the same factor as $N_k$. The nose height $d$ in Figure 2 remains fixed. Table 2 reports on the performance of all three solvers for this geometry. The proposed solution technique is the fastest for the precomputation step. It is much faster than the solver based on the original extended system formulation, especially for the case where $N_c$ is large. A factor of roughly 2.9 speed up in the precomputation is observed. Again applying the proposed solver is slightly slower than applying the HBS approximate inverse.

In the next example, $N_c$ grows by the same factor as $N_k$. The nose height $d$ in Figure 2 remains fixed. Table 2 reports on the performance of all three solvers for this geometry. The proposed solution technique is the fastest for the precomputation step. It is much faster than the solver based on the original extended system formulation, especially for the case where $N_c$ is large. A factor of roughly 2.9 speed up in the precomputation is observed. Again applying the proposed solver is slightly slower than applying the HBS approximate inverse.

Table 1: Times for applying the solution technique to (1) on the square with thinning nose geometry.

4.2 A Laplace problem with a locally refined discretization

Next we consider applying the proposed solution technique to the Laplace boundary value problem (1) where the local perturbation is a refinement in a portion of the geometry. Figure 3(a) illustrates the
geometry under consideration. It is given by the following parameterization:

\[ x(t) = \begin{pmatrix} r(t) \cos(t) \\ r(t) \sin(t) \end{pmatrix}, \text{ with } r(t) = 1 + 0.3 \sin(30t) \text{ for } t \in [0, 2\pi]. \]

The portion of the boundary being refined is highlighted in red. Figure 3(b) is a zoomed in illustration of that region. Figure 3(c) illustrates the local refinement. Three Gaussian panels \((N_c = 48)\) are replaced with \(N_p\) discretization points \((N_p/16 \text{ Gaussian panels})\). The number of discretization points on \(\Gamma_k\) remains fixed; \(N_k = 6352\).

Table 3 reports on the performance of all three solution techniques for this problem. The proposed solution technique is 13 to 21 times faster than building a new solver from scratch while applying the solver is less than a factor two slower than applying the HBS approximate inverse.

![Figure 3](image)

4.3 A Helmholtz problem with a locally refined discretization

Besides being faster than the solver for the original extended system, the proposed solver has the advantage that it can easily handle problems that are using specialized quadrature for weakly singular kernels. The issue that arises for the original extended system is that it would be cumbersome to evaluate the entries of the matrix $A_{op}$ corresponding to the interaction of $\Gamma_c$ with $\Gamma_p$. This matrix does not arise in the new extended system.

To illustrate the efficiency of the solver for systems that involve specialized quadrature we consider the following exterior Dirichlet Helmholtz boundary value problem

$$-\Delta u(x) + \omega^2 u = 0 \quad \text{for } x \in \Omega^c,$$
$$u(x) = g(x) \quad \text{for } x \in \Gamma$$

(11)

with Sommerfeld radiation condition on the sunflower geometry illustrated in Figure 3 where $\omega$ denotes the wave number. We chose to represent the solution with the following combined field

$$u(x) = \int_{\Gamma} D_{\omega}(x,y)\sigma(y) \, ds(y) - i\omega \int_{\Gamma} S_{\omega}(x,y)\sigma(y) \, ds(y),$$

(12)

where $D_{\omega}$ and $S_{\omega}$ denote the double and single layer Helmholtz kernel and $\sigma(x)$ is the unknown boundary charge distribution.

The integral equation that results from enforcing the Dirichlet boundary condition is

$$\frac{1}{2}\sigma(x) + \int_{\Gamma} D_{\omega}(x,y)\sigma(y) \, ds(y) - i\omega \int_{\Gamma} S_{\omega}(x,y)\sigma(y) \, ds(y) = g(x).$$

(13)

We discretize the operator via Nyström with a composite generalized Gaussian quadrature [7]. The wave number is set to $\omega = 20$ which corresponds to the geometry being approximately 8.3 wavelengths in size. Again, we consider the local refinement problem. Table 4 reports on the performance of the proposed solution technique and building a fast direct solver from scratch. For this problem, the proposed solver is anywhere from 15 to 35 times faster than building the fast direct solver from scratch. This speed up is the result of the increased ranks associated with Helmholtz problems. Applying the proposed solver to a right-hand-side is roughly 1.5 times slower than applying the HBS solver.

| $N_p$ | $N_p$ | $T_{new,p}$ | $T_{hbs,p}$ | $r_p$ | $T_{new,s}$ | $T_{hbs,s}$ | $r_s$ |

Table 4: Times for applying the solution techniques to (11) on the geometry in Figure 3 with local refinement.

5 Concluding remarks

This manuscript presented a new extended linear system for integral equation based solution techniques for boundary value problems on locally perturbed geometries. A fast direct solver for the new extended system is significantly faster than a fast direct solver for the original system and can be easily applied to discretizations utilizing quadrature for weakly singular kernels.
