ABSTRACT

Context. Since the discovery of its dusty disk in 1984, β Pictoris has become the prototype of young early-type planetary systems, and there are now various indications that a massive Jovian planet is orbiting the star at ∼ 10 au. However, no planets have been detected around this star so far.

Aims. Our goal was to investigate the close environment of β Pic, searching for planetary companion(s).

Methods. Deep adaptive-optics L-band images of β Pic were recorded using the NaCo instrument at the Very Large Telescope.

Results. A faint point-like signal is detected at a projected distance of ∼ 8 au from the star, within the North-East side of the dust disk. Various tests were made to rule out with a good confidence level possible instrumental or atmospheric artefacts. The probability of a foreground or background contaminant is extremely low, based in addition on the analysis of previous deep HST images. Its L’ = 11.2 apparent magnitude would indicate a typical temperature of ∼ 1500 K and a mass of ∼ 8 M_Jup. If confirmed, it could explain the main morphological and dynamical peculiarities of the β Pic system. The present detection is unique among A-stars by the proximity of the resolved planet to its parent star. Its closeness and location inside the β Pic disk suggest a formation process by core accretion or disk instabilities rather than binary like formation processes.

Key words. Instrumentation: adaptive optics – stars: early-type – stars: planetary systems – stars: individual (β Pic)

1. Introduction

Understanding planetary systems formation and evolution has become one of the biggest challenges of astronomy, since the imaging of a debris disk around β Pictoris in the 80’s (Smith & Terrile 1984) and the discovery of the first exoplanet around the solar-like star 51 Pegasi during the 90’s (Mayor & Queloz 1995). While about 20 debris disks – disks containing dust which is not primordial but produced by collisions among larger rocky bodies – have been resolved at optical wavelengths today, β Pic, a A5V star at a distance of 19+0.2 -0.1 pc (Crifo et al. 1997), remains the best studied young (12±8 Myr; Zuckerman et al. 2001) system, with an impressive amount of indirect signs pointing toward the presence of planets.

The disk shows a relative inner void of matter inside 50 astronomical units (au). Lecavelier des Etangs et al. (1995) presented intriguing light variations possibly due to disk inhomogeneities produced by a Jupiter size planet at > 6 au. Several asymmetries have been identified in the disk at optical (Kalas & Jewitt 1995; Heap et al. 2000) and infrared wavelengths, as well as a warp at ∼ 50 au (Mouillet et al. 1997; Heap et al. 2000). The structure is well reproduced by the deformation induced on colliding planetesimals by a giant planet on a slightly inclined orbit within 50 au from the star (Krist et al. 1996; Mouillet et al. 1997; Gorkavy et al. 2000; Augereau et al. 2001; Thébault & Beust 2001). Silicate dust is observed as circumstellar rings at 6, 16, and 30 au from the star (Okamoto et al. 2004), which could be explained by the presence of a 2–5 Jovian-mass (M_Jup) planet at ∼ 10 au from the star (Freistetter et al. 2007). Evaporating star grazing comets have been evidenced (see, e.g., Lagrange et al. 2000 for a review) and dynamical simulations showed that the gravitational perturbation of at least one giant planet at ∼ 10 au can account for the observed rate of evaporating bodies (Beust & Morbidelli 2000). However, no planets have been detected so far, either through direct imaging or through radial velocity studies, due to the instrumental limitations of both techniques (Galland et al. 2006). In particular, the high spatial resolution imaging detection capabilities were so far limited to distances typically ≥ 15–20 au. We used the NAOS-CONICA instrument (NaCo), installed on the Very Large Telescope UT4 (Yepun) set in Paranal (Chile), to benefit from both the high image quality provided by the Nasmyth Adaptive Optics System (NAOS; Rousset et al. 2003) at infrared wavelengths and the good dy-

namics offered by the Near-Infrared Imager and Spectrograph (CONICA;[Lenzen et al. 2003]) detector, in order to study the immediate circumstellar environment of $\beta$ Pic.

2. Observations and data reduction procedures

2.1. Observations

$L'$-band images of $\beta$ Pic ($V = 3.8, L' = 3.5$) were obtained between 2003 November 10 and 2003 November 17 with NaCo. The visible wavefront sensor was used with the 14 × 14 lenslet array, together with the visible dichroic. We used the CONICA L27 camera, which provides a pixel scale of ~ 27 mas. Saturated images of $\beta$ Pic were recorded, with detector integration times (DITs) of 0.175 s and number of detector integrations (NDIT) of 100 or 200. Every two exposure spatial offsets were applied in order to allow sky and instrumental background removal. Non-saturated images were also recorded to get images of the stellar point spread function (PSF) as well as a photometric calibration. In such case, we added the Long Neutral Density filter (transmission ~ 0.018) in the CONICA optical path, and recorded images with DITs of 0.4 s.

In addition, the binary IDS 22141S3712 (separation $\rho = 6.630 \pm 10$ mas, position angle $PA = 302.06 \pm 0.07^\circ$; van Dessel & Sinachopoulos 1993) was observed on November 11 as an astrometric calibrator. A mean plate scale of 27.105 ± 0.041 mas and a true North orientation of $-0.10 \pm 0.07^\circ$ were derived and used to calibrate all $\beta$ Pic images. Saturated and non saturated exposures were taken on the reference star HR 2435 (A0II, $V = 4.4$). The purpose is to correct for the star halo (the wings of the PSF) present in the saturated exposures. To optimize the removal of any fixed speckle, $\beta$ Pic and HR 2435 were observed, as much as possible, at close parallactic angles. Finally, twilight flat fields were also recorded in $L'$ band.

The observing conditions varied from exceptional (coherent energy $EC > 70\%$, coherent time $\tau_0 > 20$ ms) to reasonable ($EC \sim 50\%, \tau_0$ of a few ms), and sometimes poor ($EC \sim 20–35\%, \tau_0 \sim 1–2$ ms), over the run; the data quality varies accordingly. The best data set on $\beta$ Pic was obtained on November 10. In the following, we will describe the data reduction and analysis of three sets of data: (A) the very best set obtained on November 10; (B) a set of data with slightly poorer image quality obtained on the same night, with a shorter total exposure time, and (C) a set of data with poorer image quality obtained on November 13. However, Set C is representative of the best data obtained in the nights following November 10. The instrumental configurations and the status of image quality for these three data sets can be found in Table 1.

2.2. Data processing

The first step was the cosmetic correction (bad-pixels, flatfielding, background subtraction) and recentering of individual offset positions of $\beta$ Pic and HR 2435 observations. A first method was to directly apply standard routines from the eclipse library (Devillard 1997), using classical cross-correlation algorithm. A special care was taken to estimate the background at each given position by averaging images obtained at the previous and successive offset position in the observing sequence. Alternatively, a second method was used with an improved software dedicated to adaptive optics (AO) image processing (see Gratadour et al. 2005). Following a different approach for the background subtraction, images at individual offset positions were recentered using a maximum likelihood algorithm at the level of the tenth of a pixel or better. The same overall process was used for both the object and the reference. Consistent results are found in terms of recentering precision and background subtraction (at less than the background noise of 0.9 ADU).

As a second step, three parallel approaches were followed to study the close environment of $\beta$ Pic:

- first approach consists in removing the PSF wings from the saturated images of $\beta$ Pic by a simple minimization of the residuals. To do so, we first divided $\beta$ Pic images by the ones of HR 2435 obtained under similar conditions (same DIT, NDIT, and pupil position). We then computed the scaling factor to be applied to the reference in order to scale its flux to that of $\beta$ Pic. We then subtracted the reference images to the $\beta$ Pic ones. Recentering and scaling processes are repeated to minimize the residuals with respective precisions of sub-pixels and 5%. Tests have been performed using rotated images of $\beta$ Pic for PSF subtraction. However, the fact that PSF halo is not centro-symmetric and that the statical aberrations are not overlaid worsen the subtraction process.
- the second approach is to follow the same subtraction sequence but applying the maximum likelihood algorithm of Gratadour et al. 2005 (see Fig. 1). The algorithm is used here to recenter the reference star with $\beta$ Pic and therefore confirm the previous estimation. Similar precisions are achieved.
- the last approach was actually to use the MISTRAL deconvolution algorithm (Mugnier et al. 2004), based on a maximum a posteriori scheme. Nevertheless, MISTRAL relies on a strict convolution process between image and reference which is not the case for our saturated data. A first step is therefore to perform a posteriori correction of saturated part of the image and reference. This is done using a simulated
Airy pattern. The top of the Airy pattern replaces the image saturated pixels. The flux level is adjusted using the first Airy rings. Such a correction is possible because of the very good Strehl ratio on the image. Meanwhile, if this a posteriori correction does not significantly affect the restitution of the object structures, it could obviously degrade the relative photometry. Hence, the deconvolution process is an alternative approach (compared to reference subtraction and division) for the image processing which is less sensitive to image versus reference centering. It allows us to provide the best measurements of relative position with a precision of 0.3 pixels, but remain uncertain for the relative photometry due to the use of saturated images.

### 3. A candidate companion in the β Pic disk?

#### 3.1. Results from the highest-quality data (set A)

Using three independent approaches, the companion detection is confirmed at the same location. The resulting images, using the maximum likelihood algorithm for recentering, are reported in Figure 1. The companion candidate (hereafter, the CC) point-like signal is clearly visible in the divided and subtracted images. The maximum of the signal is about 190 ADU. Different techniques (variable aperture photometry, 2D-gaussian fitting, PSF-fitting) were used to extract the CC flux, giving consistent results. As the reference recentering and rescaling actually dominate the flux measurement precision, flux uncertainties were derived considering respective variations of 0.3 pixel and 5% in the subtraction process. We obtain a contrast of $\Delta L' = 7.7 \pm 0.3$ between the CC and β Pic. Using deconvolution, we derive a separation of $411 \pm 8$ mas and a PA of $31.8 \pm 1.3^\circ$ relative to the primary, i.e. along the NE side of the disk.

The use of different methods excludes artefacts created during the reduction process. In particular, the result of the deconvolution rules out any effect that could be introduced by imperfect estimation of the offset between β Pic and HR 2435 saturated images due, for instance, to a possible contribution of the disk. We did check anyway that the disk signal is very faint and not significantly asymmetric. To rule out detector effects, we looked for possible remanence and electronic ghosts that could occur because our images are saturated. Individual images inspection exclude any contamination by these two effects that rapidly disappear after a few frames. Artefacts due to the very good but still imperfect AO correction are still possible. However, aberrations due to a modulation of the deformable mirror would generally lead to the presence of either symmetrical or anti-symmetrical patterns. Static aberrations should be present equiv-

**Fig. 2.** Top left: simulated planets at PA of 150°, 210° and 330°. Top right: composite image of β Pic plus the fake planets. Bottom left: division of the composite image by the saturated image of HR 2435. Bottom right: scaled subtraction of the composite image by the saturated image of HR 2435. Note that even a slight (0.3 pixel) relative offset between β Pic and HR 2435 impacts the resulting shape of the fake planets as much as the candidate one. In particular, triangular shapes can be observed, due to the proximity of the slightly inner Airy ring.
of spatial resolution or the size of the coronographic mask prevented from getting any reliable hints of any point sources close to the star.

To our knowledge, the highest angular resolution and dynamical data available are the coronagraphic data taken in 1997 September with STIS (Heap et al. 2000). These authors were able to probe the close stellar environment down to 0′′.75 from β Pic. They did not report any CC in their images at the expected location of 0′′.9 North and 0′′.25 East to β Pic. Based on STIS detection limits and the brightness derived by Heap et al. (2000), all objects brighter $V \leq 17$ would have been detected. Red giants or supergiants can be ruled out for their distances that would bring them unrealistically far (typically $\geq 10,000$ pc) from us. If we consider a foreground or background stellar field contaminant, it would therefore have a large $(V - L \geq 5.8)$ color, i.e. a spectral type later than mid-M. Based on a number density of L dwarfs of $1.9 \times 10^{-3}$ pc$^{-3}$ given by Burgasser (2001) and Cruz et al. (2003), the probability of finding a foreground or background field L dwarf in a region of 500 mas radius around β Pic and with $L' = 11.2$ is about $10^{-10}$. Without any assumption on the contaminant spectral type, one can use galactic population model outputs to estimate the probability to find any $(L' \leq 12)$ galactic source at 500 mas from β Pic. We find a low probability of $6 \times 10^{-5}$. Last, we cannot strictly rule out a contamination by an extragalactic source, such as a high-redshift quasar. In conclusion, a contamination appears very unlikely. In addition, the fact that the candidate companion falls into the disk strongly favors that it is bound to the star.

5. Implications on the understanding of the β Pic system

With an $L'$ magnitude of $11.2 \pm 0.3$, and assuming a distance of $19.3 \pm 0.2$ pc and an age of $12^{+3}_{-2}$ Myr (Zuckerman et al. 2001), the mass of the CC is estimated to $9^{+3}_{-2} M_{\text{Jup}}$ using COND models (Baraffe et al. 2003) and $8^{+2}_{-1} M_{\text{Jup}}$ using DUSTY models (Chabrier et al. 2000). The planet should still be in the phase of cooling: Dusty and COND models predict effective temperatures of 1400 and 1600 K, respectively. The validity of these models in the case of young planets formed by core accretion has been recently questioned (Marley et al. 2007) on the basis that the accretion shock might impact the planet initial internal entropy and its subsequent early thermal evolution. These authors claim that young giant planets could be significantly cooler and fainter than predicted so far. However, the treatment of the accretion shock is still a matter of debate. The impact of the initial disk mass is also to be studied. This may be important in the present case as β Pic is significantly more massive than the Sun. In the present case, [Marley et al. 2007] model predicts a luminosity ten times fainter from what we observed for an 8 $M_{\text{Jup}}$ planet at the age of β Pic. However, we can already note that a companion at a true separation of $\sim 8$ au could not be significantly more massive than 10–20 $M_{\text{Jup}}$ since otherwise it would have been detected through radial velocity measurements, as shown by a detailed analysis that will be presented in a forthcoming paper (Desort et al., in preparation).

If the observed projected separation happens to be the physical one or close to the physical one, then the companion explains three very intriguing and so far unique characteristics of the β Pic system: the warp in the inner disk, the inner belts and the falling evaporating bodies (Freistetter et al. 2007). Mouillet et al. (1997) and Heap et al. (2000) showed that the warp of the

![Fig. 3. Top: Scaled subtraction of the composite image by the saturated image of HR 2435 for sets A, B and C. Bottom: Simulated planets at PA of 150°, 210° and 330°. disk constrains the (mass $M_p$, semi-major axis $a$) domain of the planet as follows:

$$\log(M_p/M_\star) + \log a + \log t \approx 6.7,$$

(1)

where $M_\star = 1.8 M_\odot$ (Crifo et al. 1997) and $t$ is the age of the star. Given an age $t = 12$ Myr, masses $M_p = 6$ and $13 M_{\text{Jup}}$ give $a = 9.7$ and $7.6$ au, respectively, nicely bracketing the measured projected separation. This further strengthens the likelihood that the observed CC is the planet causing the warp.

At the time of the submission of this letter, this companion was to our knowledge the first one possibly detected around an A type MS star. Recent results published since then by Marois et al. (2008) and Kalas et al. (2008) show also the presence of planets at distances 24 to 118 AU from two A types stars. This companion could be anyway the first extrasolar planet ever imaged so close to its parent star: 8 au. In particular, it would be located well inside the orbits of the outer planets of the Solar System. Its closeness and location inside the β Pic disk suggest a formation process by core accretion or disk instabilities rather than binary like formation mechanisms proposed for the companions to 2M1207 and AB Pic (Chauvin et al. 2005a, b). Further direct imaging observations should allow to constrain the planet orbit and hence measure the planet dynamical mass. This would in turn allow to test the models of planet formation. This is dramaticaly needed as the evolutionary models are not calibrated with real data in these ranges of masses and ages. Finally, we note that unfortunately, if the projected separation is the physical one, the planet orbital period is about 16 years and should be at present time much closer to the star and hence undetectable with NaCo.

Acknowledgements. We acknowledge financial support from the French Programme National de Planétologie (PNP, INSU), as well as from the French Agence Nationale pour la Recherche (ANR: project NT05 – 4,4463). These results have made use of the SIMBAD database, operated at CDS, Strasbourg, France. We also thank the ESO staff for its help during the NaCo observations. We thank J.-C. Augereau for useful discussions on the β Pic disk. AML thanks also P. Rubini for his help on the lay out of the paper. Finally, we thank the referee for his rapid and precious comments on the paper.
