Hyposplenism, antiendomysial antibodies and lymphocytic colitis in collagenous sprue

Hugh J Freeman MD

In 1970, Weinstein and colleagues (1) described a 51-year-old woman initially thought to have celiac disease, but with ongoing and refractory malabsorption despite a gluten-free diet. Detailed mucosal biopsy studies of the small intestine revealed unusual and distinctive subepithelial eosinophilic hyaline deposits with histochemical staining characteristics and ultrastructural features of collagen. As a result, this entity was labelled collagenous sprue. Extensive studies failed to reveal a specific cause, although the authors noted that a similar lesion may have been previously observed in 1947 (2). By 1980, at least 10 patients had been described (3-15), all with similar clinical and pathological features – significant malabsorption, ‘flattened’ small intestinal villous architecture with trichrome-positive subepithelial collagenous deposits, characteristic of collagenous sprue. Antiendomysial antibodies, known serological markers of celiac disease, were also detected. While collagenous sprue has been considered a distinct small intestinal disorder, the constellation of clinical and pathological findings in this patient suggests a close link with adult celiac disease.

HJ Freeman. Hyposplenism, antiendomysial antibodies and lymphocytic colitis in collagenous sprue. Can J Gastroenterol 1999;13(4):347-350. A 66-year-old woman was seen repeatedly over a decade to remove recurrent colonic adenomas and investigate episodes of watery diarrhea. Although the diarrhea was believed to be due to lymphocytic colitis, she developed weight loss, hypoproteinemia and hyposplenism that resulted in further studies, specifically to exclude celiac disease. Small intestinal biopsies, however, showed severely ‘flattened’ villous architecture with trichrome-positive subepithelial collagenous deposits, characteristic of collagenous sprue. Antiendomysial antibodies, known serological markers of celiac disease, were also detected. While collagenous sprue has been considered a distinct small intestinal disorder, the constellation of clinical and pathological findings in this patient suggests a close link with adult celiac disease.

Key Words: Celiac disease; Collagenous sprue; Diarrhea

In 1970, Weinstein and colleagues (1) described a 51-year-old woman initially thought to have celiac disease, but with ongoing and refractory malabsorption despite a gluten-free diet. Detailed mucosal biopsy studies of the small intestine revealed unusual and distinctive subepithelial eosinophilic hyaline deposits with histochemical staining characteristics and ultrastructural features of collagen. As a result, this entity was labelled collagenous sprue. Extensive studies failed to reveal a specific cause, although the authors noted that a similar lesion may have been previously observed in 1947 (2). By 1980, at least 10 patients had been described (3-15), all with similar clinical and pathological features – significant malabsorption, ‘flattened’ small intestinal villous architecture and distinctive subepithelial collagen deposits. To date, convincing evidence for histological improvement in response to different therapeutic modalities has not become available, in part because the distribution and severity of the pathological lesion are so variable (16). The precise relationship of collagenous sprue to celiac...
disease also remains quite controversial. Some have viewed collagenous sprue as a distinct small bowel disorder, while others have suggested that collagen deposition in the small bowel mucosa of patients with celiac disease is a specific morphological marker of a poor prognosis (17-19).

The present report describes a patient with recurrent episodes of watery diarrhea, initially attributed to lymphocytic colitis, a condition previously seen in celiac disease (20). In addition, weight loss and hypoproteinemia developed, and hyposplenism was later detected, which has also been described in celiac disease (21) as well as in small bowel lymphoma complicating celiac disease (22). Finally, antiendomysial antibodies, serological markers of adult celiac disease (23), were also detected. Biopsies of her small intestine, however, showed a rare mucosal disorder, collagenous sprue.

CASE PRESENTATION
A 66-year-old woman was initially evaluated in January 1985 for watery diarrhea. Fecal samples were negative for bacterial pathogens and parasites. Results of barium radiographic studies of the upper and lower gastrointestinal tract were normal. Colonoscopic biopsies revealed lymphocytic colitis and an incidental 2 cm tubulovillous adenoma with focal severe dysplasia that was treated with excisional snare polypectomy. Results of other investigations, including a hemogram, red blood cell folate, serum carotene, vitamin B12, iron and iron-binding capacity, and serum proteins with albumin, were normal. Serum levothyroxine level was normal. She was re-evaluated for diarrhea in 1986. Another dysplastic adenoma was resected, and further fecal samples were negative for bacterial pathogens and parasites. Laboratory blood test results were normal. In 1987, another adenomatous polyp was resected, and fecal cultures revealed Yersinia enterocolitica, biotype 1, serotype 6, 30. Specific treatment was not prescribed, and repeat fecal cultures were negative. Her diarrhea spontaneously resolved. In 1988 and 1989, results of additional colonoscopic evaluations were normal; no new polyps were detected and the colonic mucosa was normal on biopsy. In 1991, a severely dysplastic adenomatous polyp was resected from the cecum, but the results of another colonoscopic evaluation in 1992 were normal. Diarrhea recurred in 1993. Fecal samples were negative for bacterial pathogens and parasites. A colonoscopy showed lymphocytic colitis on biopsies but no polyps. In 1994 and 1995, colonoscopic excisions of sessile dysplastic tubular adenomas from the cecum and descending colon, respectively, were required, and her diarrhea spontaneously resolved. In 1996 and 1997, results of further colonoscopic evaluations were negative and the colonic mucosa was normal on biopsy.

In May 1998, watery diarrhea recurred and weight loss developed. The results of a flexible sigmoidoscopy and rectal biopsy were normal. Laboratory study results, including a hemogram, international normalized ratio, blood urea nitrogen, serum creatinine, electrolytes, calcium, phosphates, liver chemistry tests (aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase), immunoglobulins, serum thyroid-stimulating hormone, red cell folate, serum vitamin B12, serum iron and iron binding capacity, were normal, but her serum albumin level was reduced to 29 g/L (normal 35 to 50 g/L). The upper gastrointestinal tract was normal on endoscopy, and her stomach was normal on biopsy, with no evidence of lymphocytic (24) or collagenous gastritis (25); however, endoscopic mucosal biopsies of her duodenum (Figure 1) revealed a severe ‘flat’ small intestinal biopsy lesion, with the typical subepithelial deposits of collagenous sprue (1). A trichrome stain of these subepithelial deposits for collagen was also positive (Figure 2). Because of the ‘flattened’ biopsy appearance and resemblance to the histological features of celiac disease, a gluten-free diet was initiated. By October 1998, her weight had increased by 5 kg, but endoscopic biopsies revealed no convincing evidence of histological improvement with persistence of the subepithelial collagenous deposits. Results of repeated laboratory studies, however, were normal except for her peripheral blood smear, which showed evidence of splenic hypofunction.
with Howell-Jolly bodies (Figure 3), which are often de-
tected with celiac disease. Finally, antiendomysial antibod-
ies were detected by using human umbilical cord as a
substrate (Figure 4).

Further historical data revealed that the patient was
born in Canada and had no known family history of celiac
disease. She had no prior history to suggest an extraintesti-
nal manifestation of celiac disease, including dermatitis
herpetiformis.

**DISCUSSION**

Collagenous sprue is a rare disorder of the small intestinal
mucosa that was initially described in a patient thought to
have celiac disease with severe malabsorption (1). In spite
of a gluten-free diet, the disease persisted with refractory
malabsorption. Although cases of collagenous sprue have
only been rarely reported, the precise relationship to celiac
disease remains controversial. Some believe that the pres-
ence of pathologically significant deposits of collagen in
the lamina propria may be a marker of a poor prognosis in
patients with celiac disease, especially if these are exten-
sively present throughout the length of the small intestine.
Others believe that collagenous sprue is a truly distinct
clinical and pathological entity, entirely separate from ce-
liac disease.

In the present patient, episodes of watery diarrhea were
present for over a decade, and these were attributed to the
‘newly’ described entity of lymphocytic colitis. This form
of microscopic colitis has been previously associated with
celiac disease (20), as has collagenous colitis (26), another
more commonly detected collagenous inflammatory muco-
sal disorder (16). Although there are no prospective data
available to determine the precise frequency of these dif-
fering forms of microscopic colitis in celiac disease, col-
agenous involvement of the small and large intestinal
mucosa has been previously noted in at least one patient
(27), and collagenous gastritis (25) has been seen in a pa-
tient with lymphocytic colitis (28). The relationship pre-
vented here, however, of lymphocytic colitis and
collagenous sprue is novel.

In all previous reports of collagenous sprue, functional
hyposplenism or seromarkers, specifically antigliadin or
antiendomysial antibodies, characteristic of celiac disease,
were not detected. Thus, their detection in this patient
with collagenous sprue is not only unique but also provides
additional evidence, albeit indirect, that these apparently
separate and histologically distinct small intestinal muko-
sal disorders may be closely linked.

**ACKNOWLEDGEMENT:** The author is grateful to Dr Helen R
Gillett for performing the antiendomysial antibody testing in this
patient.
