Morphoregulatory activities of E-cadherin and beta-1 integrins in colorectal tumour cells

M. Pignatelli, D. Liu, M.M. Nasim, G.W.H. Stamp, S. Hirano & M. Takeichi

Summary
The cadherin family of adhesion molecules are prime mediators of cell-cell interactions while the integrins predominantly mediate cell-matrix and to a lesser extent cell-cell binding specificity. We have recently shown that a human colon carcinoma cell line (SW1222) organises into glandular structures, with well defined polarity when cultured in three-dimensional type I collagen gel. The current study indicates that SW1222 cells display high levels of E-cadherin (E-cd, epithelial cadherin) by western blotting and immunohistochemical staining. A monoclonal antibody (HECD-1) specific for human E-cd blocks cell-cell adhesion (100%) and inhibits (up to 75%) the glandular differentiation of SW1222 cells growing in collagen gel. Furthermore the anti-beta-1 integrin monoclonal antibody (mAb13) inhibits the glandular differentiation of SW1222 cells (61%) and their cellular binding to type I collagen (60%). However, no significant inhibition of cell-cell adhesion was demonstrated using mAb13 nor the anti-carcinoembryonic antigen monoclonal antibody (PR3B10). These results are consistent with E-cd being a cell-cell adhesion molecule expressed by SW1222 cells.

These data indicate that E-cd and beta-1 integrins mediate cell-cell and cell-collagen interactions required for the induction and maintenance of the glandular differentiation of colorectal tumour cells. Thus the down-regulation or loss of E-cd and beta-1 integrins seen in poorly differentiated colorectal tumours may represent one of the abnormalities underlying their progression towards an undifferentiated phenotype in vivo.

The induction and maintenance of a polarised and differentiated epithelial cell phenotype is a multistage process that appears to depend at least in part on the expression and function of surface adhesion receptors mediating cell-substratum as well as cell-cell interactions (Rodriguez-Boulan & Nelson, 1989). These adhesion molecules have been classified into four main groups (integrins, cadherins, immunoglobulins, selectins) (Hynes & Lander, 1992) of which integrins and cadherins comprise the main adhesion molecules expressed by normal and transformed epithelial cells (Hynes, 1992; Takeichi, 1991).

The integrins are alpha-beta heterodimeric transmembrane proteins comprising of at least 13 alpha chains and 8 beta chains which are expressed by epithelial cells as well as other cell types (Hynes, 1987, 1989). The beta-1 integrin subfamily (or Very Late Antigens, VLA) is characterised by a beta-1 integrin chain non-covalently associated with one of at least eight different alpha chains to form receptors for extracellular matrix proteins including fibronectin, laminin and collagen (Hemler, 1990). In addition some beta-1 integrins (alpha-beta-1 and alpha-beta-2 beta-1) have been shown to function as intercellular adhesion molecules in keratinocytes growing in culture medium with low calcium concentration (Larjava et al., 1990; Carter et al., 1991).

The cadherins (cds) are Ca2+ dependent cell-cell adhesion molecules that connect cells via homotypic interactions (Takeichi, 1991). They are divided into subclasses, E-cd (epithelial cadherin or uvomorulin), P-cd (placental cadherin), N-cd (neural cadherin), T-cd and V-cd which share basic structure and show a selective tissue distribution (Edelman & Crossin, 1991). When cds are functionally expressed, the inactivation of other cell-cell adhesion molecules has little effect (Duband et al., 1987), indicating that cds play a major role in intercellular physical adhesion (Takeichi, 1991). E-cd is a 120 kDa transmembrane protein which is expressed by normal epithelial cells (Shiozaki et al., 1991).

There is overwhelming evidence that the normal function of both integrins and cds is critical in the induction and maintenance of cell differentiation in vitro (Pignatelli & Bodmer, 1888; Del Buono et al., 1991; Takeichi, 1988; Takeichi, 1991). It also appears that changes in their expression and/or function occur relatively frequently in transformed cells in vivo and this is associated with loss of differentiation and relates to the biological behaviour of tumour cells (Pignatelli & Bodmer, 1990; Pignatelli et al., 1990a, 1991; Stamp & Pignatelli, 1991; Edelman et al., 1989; Shiozaki et al., 1991).

Colorectal cancer is one of the commonest cancer in Western countries in which loss or down-regulation of both integrins (Pignatelli et al., 1990a) and E-cd (Edelman et al., 1989; Shiozaki et al., 1991) has been demonstrated immunohistochemically. Changes in both integrins and E-cd were found more frequently in poorly differentiated tumours in which the architecture and the glandular configuration were greatly impaired. Therefore loss of cell adhesion molecules may explain the phenotype and biological behaviour of poorly differentiated colorectal adenocarcinomas (Pignatelli & Bodmer, 1990). To investigate the molecular mechanisms controlling the glandular differentiation of colorectal tumour cells and the role played by E-cd and beta-1 integrins, we have used a human colon carcinoma cell line (SW1222) which organises into glandular structures, with well defined polarity when cultured in three-dimensional collagen gel (Pignatelli & Bodmer, 1888; Pignatelli & Bodmer, 1989). We have investigated the effect of specific monoclonal antibodies recognising human E-cd (HECD-1) and the common beta-1 integrin chain (mAb13) on the glandular differentiation of SW1222 cells. Here we show that E-cd and beta-1 integrins mediate the cell-cell and cell-collagen interactions required for the induction and maintenance of the glandular differentiation of colorectal tumour cells.

Materials and methods

Cells
The SW1222 (Leibovitz et al., 1976) and LS174T (Rutky, 1984) human colon carcinoma-derived cell lines were maintained in Dulbecco's modified Eagle's medium (DMEM) containing 10% foetal calf serum (FCS) at 37°C in 10% CO2 in air at 100% humidity.
Collagen gel preparation

Collagen gels were prepared using Vitrogen 100 collagen (Collagen, Palo Alto, CA) according to the manufacturer's instructions. Vitrogen 100 is 95–98% type-I collagen with the remainder being type-III collagen. Cells (2 x 10^6) were mixed with 2 ml of the neutralised Vitrogen 100 collagen solution (pH 7.4 ± 0.2) and plated into 35 mm tissue culture dishes (Nunc, Roskilde, Denmark). Collagen gelation was then initiated by warming the collagen solution to 37°C for 60 min. The gel was then overlaid with 1.0 ml of DMEM/10% FCS and this mixture was changed twice a week. In some experiments the cells were resuspended in 50 μl of DMEM containing serial concentrations of the following monoclonal antibodies previously characterised: HEC-1 (human E cadherin, Shimoyama et al., 1989), mAb13 (β3 integrin, Akiyama et al., 1989), W6/32 (HLA class I, Barnstable et al., 1978). Each monoclonal antibody was also subsequently added to the cultured medium for four consecutive days. The plates were scored every day for glandular structures as follows: two hundred colonies were counted and the glandular structures identified under a phase-contrast IMT Diavert Leitz microscope (objective 32L/0.40). Glands were defined as cell aggregates composed of single columnar epithelial cells whose nuclei were polarised towards the basal surface of the cell and where cells were organised around a central lumen. Triplicate dishes were prepared for each experiment. Values were expressed as number of glandular structures per number of cell colonies. After four days, collagen gels were fixed with 10% neutral buffered formalin for 24 h, removed from the dishes, embedded in paraffin for 4 μm histological sections and stained with haematoxylin/ eosin.

Collagen binding assay

Microtitre plates (Dynatech) were coated with 50 μl/well of human type-I collagen (Sigma), human type IV collagen (Sigma), mouse laminin (Collaborative Research) and bovine serum albumin (Sigma) at serial concentrations (5, 10, 20, 40 μg/ml) and left uncovered in a laminar flow hood overnight to allow normal evaporation. The plates were then rinsed with phosphate buffered saline (PBS) and used in the binding assay. Trypsinised cells were washed three times in serum-free DMEM and resuspended in DMEM, 2.5 mg/ml BSA with serial concentrations of HEC-1 and mAb13 monoclonal antibodies. Approximately 5 x 10^4 cells per well were plated into previously coated 96-well Dynatech plates and allowed to attach for 1 h at room temperature. The supernatants were then removed and the unattached cells were washed away three times with PBS. The attached cells were fixed with 3% paraformaldehyde and stained with 0.5% toluidine blue in 3.7% parafomaldehyde. Cell attachment was estimated from absorbance measurements at 580 nm performed using an ELISA reader (Minireader II; Dynatech Labs, Inc., VA). Preliminary experiments had shown that the maximal attachment (60%) of SW1222 cells to collagen coated plates was reached after 1 h incubation (data not shown).

Cell-cell adhesion assay

This was performed as described by Benchimol et al. (1990). Briefly a single cell suspension of SW1222 cell line was obtained by 3 min incubation at 37°C with 0.12% Bacto trypsin in PBS. After centrifugation, the cells were put through a 30-gauge needle in DMEM plus 0.8% FCS. A suspension of 3 x 10^6 cells in 3 ml DMEM in 30 ml poly-styrene tubes was magnetically stirred at 37°C in an atmosphere of 5% CO2. The number of single cells was determined using a haemocytometer at time 0 and at 120 min. Duplicate cell suspensions were resuspended in DMEM containing each monoclonal antibody used for the collagen gel experiment (HEC-1, mAb13). In addition PR3B10 monoclonal antibody which recognises carcinoembryonic antigen (CEA) and the non-specific cross-reacting antigen (NCA) (Pignatelli et al., 1990b) was used.

Beta-1 integrin and E-cadherin expression by immunocytochemical staining

Colorectal carcinoma cell lines were grown on glass slides for immunocytochemical staining. For this purpose 2 x 10^6 cells were resuspended in 20 ml culture medium (DMEM/10%FCS) and plated in 9 cm Petri dishes containing autoclaved 4 well 'Multiwell' glass slides (C.A. Hendley Ltd, Essex). Cell adherence and growth on the glass slides appeared identical to that seen in plastic Petri dishes. Cells were cultured on the slides for at least 2 days prior to staining by a standard avidin-biotin-complex indirect immunoperoxidase technique.

E-cadherin expression by Western blot analysis

Freshly scraped cells were lysed for 5 min at 96°C with 4% SDS, 5% 2-mercaptoethanol in 1 ml Tris-HCl buffer (pH 6.8) followed by centrifugation at 10,000. Aliquots of 50 μg of total cell proteins in 30 μl volume were loaded per lane onto 10% SDS-polyacrylamide gel. After electrophoresis, the samples were electroblotted onto nitrocellulose sheets. The sheets were incubated with 3% bovine serum albumin (BSA) for 30 min and then with HEC-1 monoclonal antibody (20–50μg/ml) for 1 h at room temperature. After seven washes the sheets were incubated with 1:1000 diluted horse-redish peroxidase (HRP)-conjugated rabbit anti-mouse immunoglobulins (Dako, Denmark) for 1 h at room temperature. After further washes, the sheets were stained in Tris buffer (50 mM Tris-Hel, pH 7.4) containing 1-chloro-4-naphthol.

Results

Beta 1 integrin and E-cadherin expression on SW1222 and LS174T cells

To examine the expression of β3 integrins and E-cd SW1222 and LS174T cells were grown in glass slides for 48 h and then stained by avidin-biotin-complex indirect immunoperoxidase technique using specific monoclonal antibodies. In SW1222 cells, both β3 integrin chain (mAb13) and E-cd (HEC-1) were highly expressed on the cell membrane with accentuation in regions of cell-cell contacts (Figure 1a and b). The expression of E-cd on SW1222 cells was also confirmed by western blot analysis which showed the specific 120 kDa polypeptide (Figure 2, lane 1).

LS174T, which is a moderately differentiated colon carcinoma cell line with poor intercellular cohesion and no ability to undergo morphological differentiation in collagen gel (Pignatelli & Bodmer, 1989), did not express E-cadherin by western blot analysis (Figure 2, lane 2) and immunostaining (Figure 1c).

The collagen binding of SW1222 cells is mediated by β3 integrins

SW1222 cells showed specific binding to type I collagen, type IV collagen and to a lesser extent to laminin (Figure 3). The type I collagen binding of SW1222 cells was specifically inhibited by the mAb13 in a dose-dependent manner (Figure 4). The monoclonal antibody to E-cd, as predicted, did not show any specific inhibition of the SW1222 collagen binding (Figure 4).

E-cadherin is a functional cell-cell adhesion molecule expressed by SW1222 cells

To examine whether E-cd functions as an intercellular adhesion molecule on SW1222 cells, a cell aggregation assay which measures the ability of single cells to form aggregates
in suspension was used. The aggregation of SW1222 cells was completely inhibited by HECD-1 (E-cd) monoclonal antibody. Interestingly both mAb13 (β1 integrin) and an anti-CEA/NCA monoclonal antibody (PR3B10) did not significantly inhibit SW1222 cell aggregation (Figure 5).

Functional cooperation of β1 integrin and E-cadherin in the induction of glandular differentiation

To examine the functional role of β1 integrins and E-cd in the induction of the morphological differentiation of SW1222 cells in collagen gel, cells were resuspended with serial dilutions of mAb13 (β1 integrin chain) and HECD-1 (E-cd) monoclonal antibodies. The monoclonal antibody W6/32 which recognises HLA class I antigen (Barnstable et al., 1978) was used as negative control. Each monoclonal antibody was subsequently added to the cultured medium for four consecutive days. The plates were scored every day for glandular structures as described in Materials and methods. SW1222 cells grown in the presence of either HECD-1 (Figure 7a), mAb13 (Figure 7b) formed small non coherent aggregates with ill-defined margins and undifferentiated morphology. The degree of glandular differentiation of SW1222 cells was inhibited up to 61% and 75% by the addition of mAb13 and HECD-1 respectively (Figure 6). No change in the morphology of SW1222 cells was seen by adding the control antibody (W6/32) (Figure 7c).

Discussion

In malignant neoplasia cells fail to fully differentiate and show reduced adhesiveness to one another which may be an important factor in enabling them to infiltrate surrounding tissues and subsequently to detach and migrate (metastasis) (Fidler & Hart, 1982). This loss of differentiation and adhesion is reflected in the cytological and architectural structures. The morphological assessment of the glandular configuration and evaluation of the preserved polarity where cell apex and base are readily distinguished are the most
Figure 3  Binding of SW1222 cells to type I collagen (TYPE I), type IV collagen (TYPE IV), laminin (LM) and bovine serum albumin (BSA) using a cell adhesion assay. Trypsinised cells were plated into 96-well Dynatech plates previously coated with each extracellular matrix protein or BSA and allowed to attach for 1h at room temperature. Non-attached cells were washed away with PBS, and the attached cells were fixed with 3% paraformaldehyde and stained with 0.5% Toluidine blue in 3.7% formaldehyde. Cell attachment was estimated from absorbance measurements at 580 nm performed using an ELISA reader. Data shown represent the mean ± standard deviation of three determinations.

Figure 4  Inhibition of SW1222 cell attachment to type I collagen by mAb13 (βi integrin subunit). Cells were plated in microtitre wells coated with type I collagen (20 μg ml⁻¹) and containing the indicated concentrations of monoclonal antibody mAb13 (βi integrin chain) and HECD-1 (E-cadherin). As negative control no monoclonal antibody was added in some wells. Cell attachment was determined as described in Figure 3.

Figure 5  Inhibition of SW1222 intercellular adhesion by HECD-1 monoclonal antibody (E-cadherin). A single cell suspension of SW1222 cells (10⁶ ml⁻¹) was magnetically stirred at 37°C and the number of single cells determined after 2 h. Duplicate cell suspensions were resuspended in DMEM containing the following monoclonal antibodies: HECD-1 (E-cadherin), mAb13 (βi integrin chain), PR3B10 (CEA/NCA). As negative control no monoclonal antibody was added to some wells.

Figure 6  Inhibition of the glandular differentiation of SW1222 cells by HECD-1 (E-cadherin), mAb13 (βi integrin chain) and W6/32 (negative control). Cells were cultured in collagen gel in the presence of each monoclonal antibody (50 μg ml⁻¹) for 4 days. The plates were scored every day for glandular structures under a phase contrast Diavert Leitz microscope (objective 32X/0.40). Values are expressed as number of glandular structures per number of cell colonies.

reliable criteria to define the grade of malignancy of colorectal tumours (Jass et al., 1986). Thus colorectal carcinomas can be divided in three histological groups of low grade, average grade and high grade according to the degree of tubular differentiation. This classification reflects the behaviour of the tumour and significantly correlates with survival rate (Halvorsen & Seim, 1988). The molecular basis of glandular differentiation is therefore fundamental to our understanding of neoplastic cell behaviour.

In this study we show that both cell-cell and cell-collagen interactions are required for the induction and maintenance of the glandular differentiation of a colon carcinoma cell line (SW1222) in collagen gel and are primarily mediated by two classes of cell adhesion molecules, E-cad and βi integrins. We have previously shown that the ability of SW1222 cells to undergo glandular differentiation is mediated by binding to collagen I matrix via a specific cell surface receptor (Pignatelli & Bodmer, 1988). Here we demonstrate that the functional collagen receptor mediating the morphological differentiation in 3D-collagen gel is a member of the βi integrin subfamily. The known βi integrin collagen receptors expressed by SW1222 cells are αiβ1 (VLA-2) and αiβ3 (VLA-3) (Pignatelli, 1990). However, the lack of sufficient amount of a subunit-specific monoclonal antibodies has not allowed us yet to identify the βi integrin molecule mediating the glandular differentiation in collagen gel.

Cell-cell interactions are also important in morphogenesis. Studies with polarised epithelial cells grown in culture have shown that under conditions where there is no cell-cell contact, single cells exhibit a poorly differentiated phenotype
with a non polarised distribution of marker proteins of apical and basal and lateral membrane domains (Sztul et al., 1987). Recently it has become clear that cells express a multitude of cell-cell as well as cell matrix adhesion receptors which may control these complex mechanisms. Cadherins are considered to be important regulators of morphogenesis by their homophilic binding specificity. E-cad seems to mediate the selective epithelial cell adhesion which is required for the induction of glandular differentiation of SW1222. No inhibition of cell-cell interactions was seen using the anti-β1 integrin monoclonal antibody (mAb13) and the anti-β3 monoclonal antibody (PR3B10) which have been shown to function as cell-cell adhesion molecules (Larjava et al., 1990; Benchimol et al., 1989). These results are in agreement with previous reports showing that as long as cadherins are functioning, the inactivation of other adhesion systems has little effect on cell-cell adhesion (Duband et al., 1987).

Normal epithelial cells always express high levels of E-cad and β1 integrins on the cell surface. However both molecules are either lost or down-regulated in poorly differentiated colorectal as well as other malignant epithelial tumours (Pignatelli et al., 1990a; Pignatelli et al., 1991, 1992; Shiozaki et al., 1991). Interestingly in some tumours, there is heterogenous E-cad (Edelman et al., 1989; Shiozaki et al., 1991) and β1 integrin expression (Pignatelli et al., 1991, 1992) which is often confined to the cytoplasm with no clear cell surface expression. This obviously implies that in transformed cells still expressing cell adhesion molecules in the cytoplasm, the deregulation of cell-cell and cell-matrix interactions is due to loss of function with subsequent disorganisation of the cytoskeletal filaments which are structurally linked to E-cad (Takeichi, 1991) and integrins (Hynes, 1987).

There is increasing experimental evidence that low expression of E-cad and integrins seen in poorly differentiated tumours plays a major role in their biological behaviour. Frixen et al. (1991), have shown that human carcinoma cell lines with a dedifferentiated 'fibroblast-like' phenotype had lost E-cad and were highly invasive in an in vitro assay. Furthermore the invasive behaviour of dedifferentiated breast carcinoma cell lines was corrected by transfection with E-cad cDNA. Alternatively the introduction of a plasmid encoding E-cad specific antisense RNA into noninvasive transformed cells rendered the cells invasive (Vlemingkx et al., 1991) consistent with a suppressive invasive role for E-cad. Similarly Giancotti and Ruoslahti (1989) have shown by transfection experiments that the overexpression of the αβ3 integrin in Chinese Hamster Ovary cells reestablishes normal growth control in vitro with loss of tumourigenicity in nude mice. However the functional cooperation of E-cad and integrins is not fully understood. It is likely that E-cad mediates the selective adhesion by their homotypic binding allowing close contact of epithelial cells. In responsive cells which also express functional β1 integrin molecules this will allow them to fully respond to the differentiating effect of extracellular matrix proteins (Pignatelli & Bodmer, 1988). Loss of expression and/or function of E-cad and integrins will therefore allow tumour cells to dedifferentiate and lose cohesiveness, properties which would facilitate invasion and metastasis.
