**In situ investigation of NO$_x$ photocatalytic degradation: Case study in an open space office in Manchester, UK**

Julie Hot$^{1,∗}$ Paul Bradley$^2$ Jayson Cooper$^2$ Barnabé Wayser$^3$ Erick Ringot$^{1,4}$

**Abstract:** Indoor air is contaminated by numerous pollutants, which impact human health, comfort and productivity. These pollutants have various indoor sources such as building materials, furniture, combustion appliances or tobacco smoke. However, the pollution also comes from outside. In urban area, nitrogen oxides (NO$_x$) emitted into the atmosphere can reach alarming levels. These traffic-related pollutants, which seriously impact the global environment and human health, can infiltrate inside buildings. Therefore, limiting the amount of breathable NO$_x$ in outdoor and indoor environments is an important priority for the modern society. The photocatalytic process has attracted particular attention in the last two decades and has proved to be efficient to reduce the concentration of NO$_x$. However, further work has to be conducted to assess its efficiency in real indoor environments. The purpose of this paper was to report on the indoor air quality in an open space office in Manchester, UK. Focus was made on nitric oxide (NO) and nitrogen dioxide (NO$_2$). The indoor concentrations of both gases were monitored from 14 January 2019 to 7 April 2019. During this period, a photocatalytic coating was applied to a part of the indoor wall. The influence of this coating on the level of NO$_2$ was assessed by comparing the indoor concentrations before and after the application. An attention was paid to the correlation between outdoor and indoor pollution and to the effect of other parameters such as temperature, humidity, pressure and ozone (O$_3$) concentration. The results showed that the photocatalytic process led to a decrease in the NO$_x$ concentration. The likelihood to find concentrations above 35 ppb for NO and 7.5 ppb for NO$_2$ was clearly reduced after the coating application.

1 Introduction

Indoor air quality (IAQ) has become a real concern as it seriously impacts human health, comfort and productivity. Unlike outdoor air pollution, indoor air pollution remained relatively unexplored until the early 2000s. In 2006, the World Health Organization started to define guidelines for IAQ$^1$ and identified the three most problematic indoor air pollutants for public health: biological indoor air pollutants$^2$; chemical indoor air pollutants$^3$ and pollutants from indoor combustion of fuels$^4$. Building materials, decorative products and furniture are regularly mentioned as potential sources of chemical pollution in indoor environment due to their rather strong emissions of volatile or semi-volatile substances and large surface area$^5–7$. Building dampness can also reduce the quality of life of occupants as it leads to an increased exposure to various types of microorganisms (including moulds and bacteria), which emit microbial volatile organic compounds when growing on building materials$^8,9$. Moreover, IAQ is threatened by outdoor pollutants. In urban areas, nitrogen oxides (NO$_x$) and benzene, for example, are serious pollutants, which can infiltrate inside buildings$^{10–12}$. NO$_x$ is primarily made up of two pollutants, namely nitric oxide (NO) and nitrogen dioxide (NO$_2$). All combustion processes produce NO$_2$. Indoor sources are generally cooking, heating and smoking, and road transport is the main NO$_x$ outdoor source$^{13,14}$. Guideline values (indoor and outdoor) are only defined for NO$_2$ due to its serious impact on health: 200 µg/m$^3$ for short-term exposure and 40 µg/m$^3$ for long-term exposure$^{13,15}$. However, as NO easily converts to NO$_2$ in the air, it is of utmost importance to limit emissions of both NO and NO$_2$. In this end, preventive measures, which principally concern...
the transport sector, have been taken by policies [16–18]. In London, the reduction of traffic emissions is one of the main concerns of the air quality strategy [19, 20]. For example, an Ultra Low Emission Zone (ULEZ) operates since April 2019 in Central London to help to improve air quality. The same is true in France, where other actions such as grants for electrical vehicles and speed limit reduction have been taken [21].

In addition to these actions, which focus on outdoor pollution, remedial measures could be implemented to further improve IAQ, combat gaseous pollutants, such as NO$_x$ coming from outside, and reduce health effects related to air pollution. Indeed, it has to be noted that a lower IAQ guideline based exclusively on health criteria was proposed by the French organization ANSES: 20 $\mu$g/m$^3$ for long-term exposure [22]. The photocatalysis is one of the promising techniques for air purification. This process, widely documented in the literature, is based on a semi-conductor activation, TiO$_2$ being the most famous. Under irradiation, reactive species (HO, O$_2$, and HO$_2$ radicals) are created at the surface and react with pollutants to decompose or mineralize them through redox reactions [23]. The application of TiO$_2$-based coatings to building materials to degrade NO$_x$ and volatile organic compounds (VOCs) has received increasing attention in recent years and was notably studied in [24–27]. However, most of research work in the literature evaluated their efficiency at lab scale under controlled conditions, which are not representative of the real environment.

This paper focuses on the NO$_x$ indoor concentration in an open space office located in the city centre of Manchester, UK. Maintaining good IAQ in working places is indeed essential to assure health and productivity of employees. It presents a real case study, whose objective was twofold: (i) to collect data on indoor levels of NO and NO$_2$ in offices and compare them to outdoor concentrations; and (ii) to provide information on the efficiency of a photocatalytic coating (DToxGuard$^\text{TM}$ Int) to reduce NO$_x$ in an indoor environment surrounded by a highly road traffic area. It was led in collaboration with Guard Industry and LRVision companies, and the Laboratory for Materials and Durability of Construction (LMDC, University of Toulouse, France). The NO$_x$ concentration was monitored before and after the application of the coating to a small part of a wall. The results reveal a decrease both in NO and NO$_2$ concentrations, which means promising perspectives for IAQ.

## 2 Materials and Methods

### 2.1 Air quality monitor

The monitoring of the IAQ was carried out with the AQMesh$^\text{TM}$ station, which is a small-sensor air quality monitor manufactured in the UK (Environmental Instruments Ltd, Stratford-upon-Avon). According to the manufacturer, it has been designed to offer an easy-to-use and reliable air quality monitoring system that can deliver real-time localized data and analysis. This kind of device proves to be very useful in gathering air quality data in order to support initiatives to reduce air pollution and its risk to human health.

The AQMesh$^\text{TM}$ monitor was configured for measuring NO, NO$_2$ and ozone (O$_3$) concentrations in addition to temperature, humidity and atmospheric pressure. One reading was recorded every minute. More than 120,000 readings were collected during this monitoring campaign, from 14 January 2019 to 7 April 2019. This time period included the pre-air quality monitoring (from 14 January 5 pm to 4 March 2019 midnight) before the coating application. The aim was to gather background data and have a reference in order to assess the influence of the DToxGuard$^\text{TM}$ Int product on the NO$_x$ concentration (from 6 March to 7 April 2019 midnight).

### 2.2 Site description

The monitoring campaign was conducted in Sir Robert M’Alpine (SRM) office in Manchester, UK. Figure 1 shows pictures of the open space office, in which the AQMesh$^\text{TM}$ air quality monitor was placed on the wall, on which the photocatalytic coating was applied.

![Figure 1](image1.png) **Figure 1.** Interior views of Sir Robert M’Alpine office. The AQMesh$^\text{TM}$ air quality monitor was placed on the wall between two windows

Before starting the monitoring campaign, information on site location, surrounding area and open space office characteristics were gathered. They are summarized in Table 1. The site of investigation was in the city centre of Manchester, an area of heavy traffic. Figure 2 shows the location of the SRM building, which is surrounded by two automatic air monitoring stations managed by the Manchester City Council.

### 2.3 Photocatalytic coating and application

Guard Industry and LR Vision companies have been working on the air quality issue since 2009. They own a French patent on water based photocatalytic coatings...

and have investigated the air depollution application of the photocatalysis in collaboration with the LMDC. DTtoxGuard® is a two-component product that was carefully mixed before use. After mixing it consists of a photocatalytic dispersion containing 6 wt% of dry matter TiO₂. Then, to ensure the application was controlled, DTtoxGuard® Int was applied by brush (2 layers) and windows were opened to provide adequate ventilation (Figure 3(a)). For this experiment, the treated wall surface consisting of painted plaster was only 2.88 m², which corresponded to the area of wall where the AQMesh® air monitor was hung on, from window to window, and floor to ceiling. Once the application was completed, the appearance of the substrate remained unchanged (Figure 3(b)). The wall was coated on 5 March 2019.

Figure 3. (a) Application of DTtoxGuard® Int by brush and windows opened; (b) After completion: the AQMesh® air quality monitor was setup on the treated wall.

Moreover, to keep SRM employees informed of the process, Guard Industry created the sign showed in Figure 4 to give a simplistic explanation of how DTtoxGuard® Int works.
3 Results

3.1 NO and NO₂ indoor concentrations

The evolutions of NO and NO₂ indoor concentrations as a function of time are shown in Figure 5(a), 5(b) respectively. The DtoxGuard® Int coating was applied to the wall on the 5th of March 2019.

These data highlight the significant variations of NO and NO₂ concentrations during the day and from day to day inside the SRM office. Before the application of DtoxGuard® Int (14 January 2019 – 4 March 2019), the NO indoor concentration ranged from 0 to 125 ppb and was most of the time below 80 ppb. Several peaks above 100 ppb were measured and the NO indoor concentration reached exceptionally a peak at 177 ppb. Its mean value was 38 ppb. The NO₂ concentrations were lower than those for NO, between 2 ppb and 17 ppb with a peak at 21 ppb, and inferior to the outdoor limit defined for long-term exposure (40 µg/m³ ≈ 21.3 ppb). Its mean value was 7.30 ppb. The evolution trends for both gases were similar to the ones reported in the literature. In an earlier study, Ekberg compared the supply air and the exhaust air in office buildings located in traffic-influenced environments. He reported NO₂ concentrations in the exhaust air for one building investigated: the values were lower than in the supply air and ranged from 6 to 24 ppb. For NO, the concentrations varied between 0 and 100 ppb, with a peak value at 180 ppb[10]. Challoner and Gill investigated the indoor air in commercial buildings located along busy street canyons in Dublin’s city centre. They measured a daily variation in NO₂ concentration, which ranged from 5 to 30 ppb depending on the ventilation systems and NO₂ outdoor concentration[12]. Moreover, Mandin et al. sampled the air in office buildings across Europe in summer and winter in the frame of the OFFICAIR project. For each building investigated they used a passive sampling technique, which did not allow measuring the daily variations as shown in Figure 5(a) and Figure 5(b). During the winter campaign, the minimum, maximum and mean NO₂ indoor concentrations were 4.8 µg/m³ (≈ 2.55 ppb), 39 µg/m³ (≈ 20.75 ppb) and 18 µg/m³ (≈ 9.57 ppb) respectively[28].

A change in the concentration evolutions occurred after the application of DtoxGuard® Int (6 March 2019 – 7 April 2019). For NO pollutant, a narrower range of variations was observed and only few peaks were monitored. The concentrations were mostly inferior to 50 ppb. For NO₂, although the change was less pronounced, the concentrations seemed to move towards lower values, mainly below 10 ppb. The mean values for NO and NO₂ were 23.43 ppb and 5.87 ppb, which corresponded to a decrease of roughly 38% and 20% compared to the period before the coating application (14 January 2019 – 4 March 2019).
3.2 NO and NO\textsubscript{2} outdoor concentrations

NO and NO\textsubscript{2} outdoor concentration evolutions collected by the two automatic air monitoring stations are shown in Figure 6(a), 6(b) respectively. These data were downloaded from the Air Quality England website for the period investigated, from 14 January 2019 to 7 April 2019\textsuperscript{29}. The same pattern of evolution was observed for the two sites but the concentrations monitored by the station located at Oxford Road were much higher. Such amplitude differences can notably be explained by the short distance between the stations and the A57 Manchester road (Figure 2). Indeed, the influence of traffic-related air pollutants is expected to decrease with increasing distance of the site to the highway\textsuperscript{30}.

![Figure 6](image)

**Figure 6.** (a) NO outdoor concentrations monitored by the Oxford Road and Picadilly stations; (b) NO\textsubscript{2} outdoor concentrations monitored by the Oxford Road and Picadilly stations (data were downloaded from the Air Quality England website). Notice the different scales.

The indoor and outdoor concentrations of NO and NO\textsubscript{2} are plotted in Figure 7(a), 7(b) respectively. The curves “Average NO outdoor” and “Average NO\textsubscript{2} outdoor” correspond to the means of the concentrations monitored by each station, as the SRM building is approximately halfway located. An indoor/outdoor correlation was observed as reported by previous studies\textsuperscript{12,31–33}. Outdoor and indoor concentrations followed the same pattern, with indoor concentrations being lower.

![Figure 7](image)

**Figure 7.** (a) NO outdoor and indoor concentrations; (b) NO\textsubscript{2} outdoor and indoor concentrations. The outdoor concentration curves correspond to the mean of the concentrations monitored by each station (cf. Figure 6). Notice the different scales.

Table 2 summarizes the mean and maximum values of indoor and outdoor concentrations for both gases and each period (before and after DtoxGuard\textsuperscript{®} Int application). The indoor/outdoor ratios calculated from the mean values were also reported: ≈ 0.53 and ≈ 0.22 for NO and NO\textsubscript{2} respectively. With no contribution from indoor sources (as it could be the case in houses), outdoor concentrations, which were attenuated by the building envelope, were the primary factor in determining the indoor level of NO\textsubscript{x}. Colbeck found that the indoor/outdoor ratios for NO\textsubscript{2} varied from 0.34 to 0.54 with an average value of 0.44 in two shops in Colchester (UK)\textsuperscript{31}. The same trends were noted by Kukadia et al. who reported a reduced level of external pollutants such as NO and NO\textsubscript{2} inside two buildings in Birmingham (UK): the transient peak concentrations were approximately divided by two\textsuperscript{32}. Moreover, Phillips et al. characterized three offices in Central London with respect to air quality. They found that outdoor levels of NO\textsubscript{x}, NO\textsubscript{2} and NO exceeded indoor levels: the indoor/outdoor ratios calculated from the mean values were between 0.21 and 0.59 for NO\textsubscript{2} and 0.33 and 0.80 for NO\textsuperscript{33}. 
Table 2. Mean and maximum values of indoor and outdoor concentrations for NO and NO\textsubscript{2} before and after DtoxGuard\textsuperscript{®} Int application. The I/O (Indoor/Outdoor) ratios were calculated from the mean values

| Values                  | Before DtoxGuard\textsuperscript{®} Int application | After DtoxGuard\textsuperscript{®} Int application |

4 Discussion

4.1 Likelihood analysis

A decrease in NO indoor concentrations and, to a lesser extent in NO\textsubscript{2} indoor concentrations, was observed from the 6\textsuperscript{th} of March 2019 (Figure 5(a), 5(b) and Table 2). It could be due to: (i) the decrease in the outdoor pollution as both indoor and outdoor concentrations were correlated (cf. part 3.2), and/or (ii) the photocatalytic activity of the DtoxGuard\textsuperscript{®} Int coating. In order to define the role of each phenomenon in changing the levels of NO and NO\textsubscript{2}, and draw conclusions on the efficiency of the photocatalytic activity, the authors conducted further analyses of the raw data. They suggested comparing the likelihood of exceeding a certain concentration threshold before and after the DtoxGuard\textsuperscript{®} Int application. Results are presented in Figure 8. The chosen thresholds were 40, 35, 20, 15 and 5 ppb for NO, and 15, 10, 5, 7.5 and 2.5 ppb for NO\textsubscript{2}. The probability that the NO or NO\textsubscript{2} concentration was above the defined threshold during the period investigated was quantified by a percentage. Firstly, it can be noted that, for both gases, the indoor and outdoor percentages calculated before the DtoxGuard\textsuperscript{®} Int application (from 14 January 2019 to 4 March 2019) reached higher values than the ones obtained after the DtoxGuard\textsuperscript{®} Int application (from 6 March 2019 to 7 April 2019). The difference was less pronounced for the lowest thresholds (15 and 5 ppb for NO; 5 and 2.5 ppb for NO\textsubscript{2}).

Moreover, the ratios between indoor and outdoor percentages were calculated for the two periods investigated (before and after the DtoxGuard\textsuperscript{®} Int application). These values are summarized in Table 3 and presented on two radar charts in Figure 9. If the decrease in the outdoor concentrations was the only phenomenon at the origin of the observed decrease in the indoor concentrations after the DtoxGuard\textsuperscript{®} Int application, similar indoor/outdoor ratios before and after the DtoxGuard\textsuperscript{®} Int application should be expected for a same threshold. For NO, this was true for 5 ppb, 15 ppb and 20 ppb: the indoor/outdoor ratios were 1.143, 1.192 and 1.083 after the DtoxGuard\textsuperscript{®} Int application and 1.064, 1.138 and 1.148 before the DtoxGuard\textsuperscript{®} Int application. However, the ratios significantly decreased after the DtoxGuard\textsuperscript{®} Int application for the 35-ppb and 40-ppb thresholds (0.249 and 0.136 respectively). They were 3 and 4.60 times lower than the ones before the DtoxGuard\textsuperscript{®} Int application. In the case of NO\textsubscript{2}, the ratios for the 7.5-ppb and 10-ppb thresholds were 2.60 and 15 times lower respectively. The differences between indoor/outdoor ratios after the DtoxGuard\textsuperscript{®} Int application and those before the coating application are clearly visible on Figure 9 for the highest thresholds. This means that something else was happening, which led to a decrease in the peaks of the NO and NO\textsubscript{2} indoor concentrations and limited the concentration variations after the DtoxGuard\textsuperscript{®} Int application. The authors reasonably thought that this was due to the photocatalytic activity. DtoxGuard\textsuperscript{®} Int contains TiO\textsubscript{2} semiconductor particles, which were activated under the natural and artificial light in the SRM office. Redox reactions were then promoted to decompose NO\textsubscript{2}. Such process has been well documented in the literature\textsuperscript{[37, 38]}.

DtoxGuard\textsuperscript{®} Int coating was also used in a previous study, in which it was applied to the walls (a surface of 9.3 m\textsuperscript{2} was covered) in a 10-m\textsuperscript{3} experimental chamber. The authors reported high NO degradation rates under UV and visible light\textsuperscript{[37, 38]}. 
4.2 Correlation coefficients

During this experimental campaign, other parameters than NO and NO\textsubscript{2} indoor concentrations were monitored by the AQMesh\textsuperscript{®} station: O\textsubscript{3} concentration, temperature, humidity and atmospheric pressure. In order to assess the influence of these parameters on NO and NO\textsubscript{2} concentration variations, correlation coefficients (between two parameters) were calculated according to Equation 1. Table 4 summarizes the correlation coefficients (absolute value) obtained.

\[
\text{Correlation} \ (X, \ Y) = \frac{\sum (x - \bar{x})(y - \bar{y})}{\sqrt{\sum (x - \bar{x})^2 \sum (y - \bar{y})^2}}
\] (1)

Where x and y are the parameters investigated and \(\bar{x}\) and \(\bar{y}\) are the mean values.

As shown in Table 4, the correlation coefficients between the investigated parameters were inferior to 0.5 except for NO\textsubscript{2} and O\textsubscript{3} concentrations, for which the coefficient was 0.717. The chemical coupling of these two gases has been discussed in previous studies\cite{40-42}. Ozone is indeed a secondary photochemical pollutant that is produced from anthropogenic precursors, such as traffic emissions. NO\textsubscript{2} is mainly produced via NO in combustion processes by oxidation of nitrogen. NO\textsubscript{2} then acts as a precursor of O\textsubscript{3} and has a major impact on its daily variation: a reduction in the level of NO\textsubscript{2} is accompanied by an increase in the level of O\textsubscript{3}. Such variation was notably discussed in\cite{42}. To a lesser extent, the coefficients revealed a correlation between NO and NO\textsubscript{2} (0.368), and between both gases with temperature (0.412 for NO/Temp. and 0.0337 for NO\textsubscript{2}/Temp.)\cite{43}.

According to the authors, the correlation of NO and NO\textsubscript{2} with the other parameters could not explain the decrease in NO and NO\textsubscript{2} concentrations observed from the 6\textsuperscript{th} of March 2019. This analysis corroborated the previous one (cf. part 4.1), which attributed the decrease in the concentrations of NO and NO\textsubscript{2} to both above mentioned phenomena, i.e. the photocatalytic activity of the coating and the overall decrease in ambient air pollution.

5 Conclusion

This case study provides detailed information on the IAQ in an open space office in Manchester, UK. The indoor concentrations of NO and NO\textsubscript{2} were monitored during 84 days, from 14 January 2019 to 7 April 2019 with the AQMesh\textsuperscript{®} air quality station. On the 5\textsuperscript{th} of March, a photocatalytic coating was applied to a small part of an indoor wall. The collected data showed that the indoor and outdoor concentrations of NO and NO\textsubscript{2} significantly varied during the day and from day to day. The indoor concentrations were correlated to the outdoor pollution: the indoor/outdoor ratios were found to be around 0.53 for NO and 0.22 for NO\textsubscript{2}. A decrease in NO and NO\textsubscript{2} concentrations was observed from the 6\textsuperscript{th} of March. The authors showed that this decrease was both due to the decrease in outdoor pollution and to the photocatalytic degradation of NO and NO\textsubscript{2}. They notably assessed the likelihood that the concentrations of NO and NO\textsubscript{2} exceeded a certain threshold and compare the results obtained before and after the photocatalytic coating application. This analysis showed that the DtoxGuard\textsuperscript{®} Int coating limited the concentration variations and reduced the peaks of NO and NO\textsubscript{2}: the likelihood of exceeding 30 ppb for NO and 7.5 ppb for NO\textsubscript{2} was 3 times and 2.60 times lower after the coating application respectively. Given the influence on numerous parameters on NO\textsubscript{3} concentration, this paper reported an original approach to assess the response of a photocatalytic coating in a real

Table 3. Ratios between indoor (I) and outdoor (O) percentages for each threshold

| Threshold (ppb) | Before DtoxGuard® Int application | After DtoxGuard® Int application |
|----------------|-----------------------------------|----------------------------------|
|                | 14 January 2019 - 4 March 2019    | 6 March 2019 - 7 April 2019      |
| I/O ratio for NO | 0.626 0.742 1.148 1.138 1.064     | 0.136 0.249 1.083 1.192 1.143    |
| I/O ratio for NO\textsubscript{2} | 0.004 0.166 0.442 0.809 0.996 | 0 0.011 0.17 0.682 1 |

Table 4. Correlation coefficients (absolute value). Each coefficient was calculated between two parameters. The parameters investigated were: NO, NO\textsubscript{2} and O\textsubscript{3} concentrations, temperature, humidity and atmospheric pressure. The highest correlation coefficient is in bold

| Time          | NO  | NO\textsubscript{2} | O\textsubscript{3} | Temp. | Humidity | Atm. Press. |
|---------------|-----|---------------------|-------------------|-------|----------|------------|
| Before DtoxGuard® Int application | 1 | 0.304 | 0.237 | 0.193 | 0.155 | 0.084 | 0.204 |
| After DtoxGuard® Int application | NO | 1 | 0.367 | 0.105 | 0.412 | 0.03 | 0.264 |
| NO\textsubscript{2} | 1 | 0.717 | 0.337 | 0.247 | 0.136 | 1 | 0.218 |
| O\textsubscript{3} | 1 | 0.101 | 0.194 | 0.079 | 1 | 0.137 | 1 |
Figure 8. Likelihood of exceeding a concentration threshold: (a) for NO indoor and outdoor concentrations before the DtoxGuard® Int application; (b) for NO indoor and outdoor concentrations after the DtoxGuard® Int application; (c) for NO₂ indoor and outdoor concentrations before the DtoxGuard® Int application; (d) for NO₂ indoor and outdoor concentrations after the DtoxGuard® Int application.

Figure 9. Radar charts showing the indoor/outdoor ratios obtained for each threshold before and after the DtoxGuard® Int application: a) for NO and b) for NO₂.

indoor environment. It has to be kept in mind that the coated surface in the presented study was small (2.88 m²), which means that a higher decrease in indoor pollution could be expected.
