Recent developments in semiconductor-based spintronics and quantum computation have generated intense interest in examining the spin dynamics in a wide range of semiconductor material systems at telecom wavelengths due to their potential applications in spin-dependent optical modulators and switches for optical telecommunications. The optical wavelengths of 1.31 \( \mu m \) and 1.55 \( \mu m \) allow a minimum dispersion and signal loss in standard silica-based fiber-optic networks. Spin-dependent all-optical switching in semiconductor quantum well etalons and spin-dependent ultrafast optical gain modulation in microcavities have been recently demonstrated. In addition, differential quantum efficiency as high as 64% is attainable for all-epitaxially grown telecom-wavelength vertical cavity surface emitting lasers (VCSELs) with InP lattice-matched AlInGaAs alloys for quantum well active regions and AlGaAsSb alloys for highly reflective distributed Bragg reflectors operating above room temperature. The possibility of integrating laser sources, optical modulators, and optical switches on a single photonic integrated chip with added functionalities based on spin degrees of freedom makes AlInGaAs alloys ideal candidates for spintronics.

In this letter, we present room temperature measurements of the electron spin coherence times and effective g-factors in AlInGaAs multiple quantum wells, which are optimized active regions of VCSELs with wavelengths in the range 1.26 – 1.53 \( \mu m \) designed for optical telecommunication applications. We characterize the samples using photoluminescence and measure the electron spin dynamics using pump-probe optical spectroscopy. The electron effective g-factors and spin coherence times are found to vary with aluminum alloy concentration from −2.3 to −1.1 and from 50 ps to 100 ps, respectively.

Our samples are comprised of a set of quaternary alloy AlInGaAs multiple quantum wells grown using digital alloy molecular beam epitaxy. These samples are composed of digital alloys of ternaries (Ga\(_{0.47}\)In\(_{0.53}\)As and Al\(_{0.45}\)In\(_{0.55}\)As, referred to as GaInAs and AlInAs, respectively) lattice-matched to InP. The sample structure is of the form: AlInAs/(AlIn)\(_r\)(GaIn)\(_x\)As/5x[(AlIn)\(_y\)(GaIn)]\(_{1-y}\)As/(AlIn)\(_x\)(GaIn)\(_{1-x}\)As/(AlIn)\(_y\)(GaIn)\(_{1-y}\)As/5x[(AlIn)\(_y\)(GaIn)]\(_{1-y}\)As/(AlIn)\(_y\)(GaIn)\(_{1-y}\)As/(AlIn)\(_y\)(GaIn)\(_{1-y}\)As/(AlIn)\(_y\)(GaIn)\(_{1-y}\)As/InP substrate, shown schematically in Fig.1(a). All samples are undoped. The photoluminescence (PL) spectra of these samples are excited non-resonantly with 2.5 mW of 800 nm light from a tunable mode-locked Ti:sapphire laser and measured using a liquid nitrogen cooled InGaAs photodiode array detector [Fig. 1(b)]. The PL peaks of the samples at room temperature occur at 1.53 \( \mu m \) (Sample A), 1.34 \( \mu m \) (Sample B), 1.30 \( \mu m \) (Sample C), and 1.26 \( \mu m \) (Sample D), and the corresponding energies are 0.811 eV, 0.925 eV, 0.954 eV, 0.990 eV, respectively.
The electron spin dynamics. An optical parametric amplifier pumped by a regeneratively amplified Ti:sapphire mode-locked laser produces \( \sim 200 \) fs duration pump and probe pulses tunable from 1.1 \( \mu m \) to 1.65 \( \mu m \) with a repetition rate of 100 kHz, whose relative delay is adjusted by a mechanical delay line. The helicity of the pump beam for spin injection is modulated with a photoelastic modulator at 42 kHz, and the linearly polarized probe beam for spin detection is mechanically chopped at a frequency of 800 Hz. The pump and probe beams are focused to a spot size of \( \sim 50 \mu m \) on the sample, which is mounted between the two poles of an electromagnet which produces a magnetic field \( B \) up to 0.6 T and perpendicular to the direction of the pump and probe beams. The circularly polarized pump beam excites electron and hole spins which precess at the Larmor frequency around the transverse applied magnetic field. The typical pump and probe powers used in the measurements are 1 mW and 0.1 mW, respectively. The rotation of the linear polarization axis of the probe beam is proportional to the net electron spin polarization along the probe’s normal incidence. Using a balanced photodiode bridge combined with a lock-in detection technique, the electron spin precession is measured with subpicosecond temporal resolution.

In Fig. 2, we show representative TRKR scans for Sample A (8% Al) and Sample D (18% Al) at room temperature with applied magnetic fields \( B = 0 \) T and \( B = 0.6 \) T. The electron spin magnetization precesses in the plane perpendicular to the applied magnetic field, and the Kerr rotation angle as a function of time delay \( \Delta t \) can be described by an exponentially decaying cosine: \( \theta(\Delta t) = \theta_0 \exp(-t/T_2^*) \cos(2\pi\nu_L \Delta t) \), where \( \theta_0 \) is the initial amplitude of the electron spin polarization, \( \nu_L \) is the Larmor precession frequency \( \nu_L = g^* \mu_B B/\hbar \), where \( g^* \) is the effective in-plane electron g-factor of electrons in the quantum wells, \( \mu_B \) is the Bohr magneton, \( \hbar \) is Planck’s constant, and \( T_2^* \) is the electron spin coherence time. The data are fit by adjusting the parameters \( \theta_0 \), \( T_2^* \), and \( g^* \). The lack of additional frequency components and the agreement of \( g^* \) with the expected value for electrons indicate that hole spin precession is not observable.

The magnetic field dependence of \( T_2^* \) at room temperature for all four samples is plotted in Fig. 3(a). All the samples exhibit weak magnetic field dependence. The corresponding Larmor frequencies \( \nu_L \) of all samples have a linear magnetic field dependence [Fig. 3(b)], yielding \( |g^*| = 2.31 \) (Sample A), \( |g^*| = 1.49 \) (Sample B), \( |g^*| = 1.47 \) (Sample C), and \( |g^*| = 1.07 \) (Sample D). Although
the sign of \( g^* \) cannot be determined from our measurements, the fact that bulk InAs has a large and negative g-factor, while bulk AlAs has a small positive g-factor indicates that \( g^* \) is negative. The electron effective g-factor as a function of \( \rho_w \) at room temperature is plotted in Fig. 4(a), showing \( g^* \) increases with increasing \( \rho_w \) consistent with the expected trends.

The electron spin coherence time \( T_2^* \) as a function of \( \rho_w \) at room temperature with applied magnetic field \( B = 0.6 \text{ T} \) is displayed in Fig. 4(b). The measured electron spin coherence times are in the range from 50 ps to 100 ps. \( T_2^* \) increases with increasing \( \rho_w \) except for Sample C. The observed nonlinear \( \rho_w \) dependence of \( T_2^* \) is due to the combined effects of orbital scattering and internal effective magnetic field in the quantum wells.

Electron spin relaxation near room temperature is dominated by the D'yakonov-Perel' mechanism, and the spin relaxation rate is \( T_2^{-1} \propto \Omega^2 \tau_o \), where \( \Omega \) is the momentum-dependent precession frequency about the internal effective magnetic field of the quantum wells and \( \tau_o \) is the orbital coherence time, which is proportional to the electron mobility \( \mu \). As \( \rho_w \) increases, \( \Omega \) increases due to band structure effects on the effective internal magnetic field, causing \( T_2 \) to decrease with increasing \( \rho_w \). To illustrate these effects, we calculate the spin coherence times \( T_2 \) as a function of \( \rho_w \) for Samples A-D assuming a constant mobility for all samples using a generalized 14-band \( K \cdot p \) envelope-function theory, and the results are shown in Fig. 4(c). However, the observed trends in \( T_2^* \) might be partly due to the nonlinear \( \rho_w \) dependence of the electron mobility in these samples. As \( \rho_w \) increase, \( \tau_o \) decreases due to orbital scattering, causing \( T_2 \) to increase with increasing \( \rho_w \). Finally, imperfection in crystal growth may lead to structural inversion asymmetry in the quantum wells, which generates an additional internal effective magnetic field contributing to electron spin decoherence.

We have measured the electron spin coherence times and electron spin precession frequencies in telecommunication wavelength quaternary multiple quantum wells and observed the electron spin coherence times of \( \sim 100 \text{ ps} \) at room temperature. Our measurements reveal that the electron effective g-factor can be tuned by varying the aluminum alloy concentration. These results demonstrate the possibility of optical modulation using spin manipulation in this material system.
