Probabilistic Matching of Planar Regions

Helmut Alt        Ludmila Scharf        Daria Schymura
Institut für Informatik, Freie Universität Berlin

Abstract

We analyze a probabilistic algorithm for matching shapes modeled by planar regions under translations and rigid motions (rotation and translation). Given shapes $A$ and $B$, the algorithm computes a transformation $t$ such that with high probability the area of overlap of $t(A)$ and $B$ is close to maximal. In the case of polygons, we give a time bound that does not depend significantly on the number of vertices.

1 Introduction

The Problem. Matching two geometric shapes under transformations and evaluating their similarity is one of the central problems in computer vision systems where the evaluation of the resemblance of two images is based on their geometric shape and not color or texture. Because of its significance the problem has been widely covered in the literature, see [3, 10] for surveys.

Depending on the application, 2D shapes are modeled as finite point patterns, polygonal chains or polygons. Given two shapes $A$ and $B$, as well as a set of transformations $T$ and a distance measure $d$, the problem is to find the transformation $t \in T$ such that $t(A)$ and $B$ match optimally with respect to $d$. Two shapes are considered similar if there is a transformation $t$ such that the distance between $t(A)$ and $B$ is small. The problem is well-studied for various settings, e.g., sets of line segments, rigid motions and the Hausdorff distance.

In this paper we consider the problem of matching 2D shapes modeled by plane open sets, e.g., sets of polygons, with respect to the area of the symmetric difference, which is the area that belongs to exactly one of the shapes. As sets of allowed transformations $T$ we will consider the set of translations and the set of rigid motions (rotation and translation) in the plane. Minimizing the area of the symmetric difference under translations or rigid motions is equivalent to maximizing the area of overlap, so we will consider the latter formulation of the problem for the rest of this article. The area of overlap is a well-known similarity measure, and, e.g., has the advantage that it is insensitive to noise. Furthermore, computing the maximal area of overlap of two sets of polygons under translations or rigid motions is an interesting computational problem on its own.

Related Work. For simple polygons, efficient algorithms for maximizing the area of overlap under translations are known. Mount et al. [11] show that the maximal area of overlap of a simple $n$-polygon with a translated simple $m$-polygon can be computed in $O(n^2m^2)$ time. Recently, Cheong et al. [6] introduced a general probabilistic framework for computing an approximation with prespecified absolute error $\varepsilon$ in $O(m + (n^2/\varepsilon^4) \log(n)^2)$ time for translations and $O(m + (n^3/\varepsilon^4) \log(n)^5)$ time for rigid motions.

De Berg et al. [7] consider the case of convex polygons and give a $O((n + m) \log(n + m))$ time algorithm maximizing the area of overlap under translations. Alt et al. [2] give a linear time constant factor approximation algorithm for minimizing the area of the symmetric difference of convex shapes under translations and homotheties (scaling and translation).

For higher dimensions Ahn et al. present in [1] an algorithm finding a translation vector maximizing the overlap of two convex polytopes bounded by a total of \( n \) hyperplanes in \( \mathbb{R}^d \) for \( d \geq 3 \). Their algorithm runs in \( O(n^{\lceil d/2 \rceil} + 1 \log^{d-1} n) \) time with probability at least 1 – \( n^{-O(1)} \).

Surprisingly little has been known so far about maximizing the area of overlap under rigid motions.

**Overview.** We will design and analyze a simple probabilistic matching algorithm, which for translations works as follows. Given two shapes \( A \) and \( B \), in one random experiment we select a point \( a \in A \) and a point \( b \in B \) uniformly at random. This tells us that the translation \( t \) that is given by the vector \( b - a \) maps some part of \( A \) onto some part of \( B \). We record this as a vote for \( t \) and repeat this procedure very often. Then we determine the densest cluster of the resulting point cloud and output the center of this cluster as a translation that maps a large part of \( A \) onto \( B \). For rigid motions we consider two different approaches for the vote generation in one random experiment.

We show that the algorithm approximates the maximal area of overlap under translations and rigid motions. More precisely, let \( t^{\text{opt}} \) be a transformation that maximizes the area of overlap of \( A \) and \( B \), and let \( t^* \) be a transformation computed by the algorithm. Given an allowable error \( \varepsilon \) and a desired probability of success \( p \), both between 0 and 1, we show bounds on the required number of random experiments, guaranteeing that the absolute difference between approximation and optimum \( |t^{\text{opt}}(A) \cap B| - |t^*(A) \cap B| \) is at most \( \varepsilon |A| \) with probability at least \( p \). Here \( |\cdot| \) denotes the area (Lebesgue measure) of a set. Furthermore, we prove that this algorithm computes a \((1+\varepsilon)\)-approximation of the maximal area of overlap under translations and rigid motions, meaning that \( |t^{\text{opt}}(A) \cap B| - |t^*(A) \cap B| \leq (1 + \varepsilon)|t^{\text{opt}}(A) \cap B| \) with high probability, if we make a reasonable assumption about the input shapes.

This algorithm is a special case of a probabilistic algorithmic scheme for approximating an optimal match of planar sets under a subgroup of affine transformations. Alt and Scharf [4] analyzed another instance of this algorithmic scheme that compares polygonal curves under translations, rigid motions, and similarities.

## 2 The Algorithms

### 2.1 Description of the Algorithms

**Shapes.** We consider shapes modeled by open bounded, and therefore, Lebesgue measurable subsets of the plane. We always assume the shapes to have positive area. Additionally, we assume that there is a method to select uniformly distributed random points from a shape and the density function is Lipschitz continuous (see Section 3.2). This is the case for sets of disks and for sets of polygons, or equivalently, sets of triangles, which probably is the most common representation in practice. The idea of the algorithm can be applied to bitmap data as well.

For a shape represented by \( n \) triangles a random point can be generated by first selecting a triangle randomly with probability proportional to the relative area of the triangle and then selecting a random point from that triangle.

For an arbitrary Lebesgue measurable set \( A \) in the plane if we are given a set of triangles \( T \) it is contained in, and an algorithm that decides “Is \( p \in A \)?”, we can sample uniformly at random from \( \bigcup T \) and discard points that are not in \( A \). The density function is Lipschitz continuous, for example, if the shape boundaries are unions of piecewise differentiable simple closed curves.

**General Idea.** The idea of the algorithm is quite simple. Given two shapes \( A \) and \( B \), repeat the following random experiment very often, say \( N \) times: Select random point samples of appropriate size from each shape and compute a transformation that maps the point sample of one shape to the sample of the other shape. Keep this transformation, called a “vote”, in mind. In each step, we grow our collection of “votes” by one. Clusters of “votes” indicate transformations that map large parts of the shapes onto each other.
Every translation can be associated with a point in two dimensional space and every rigid motion with a point in three dimensional space. The densest cluster of “votes” is then defined as the transformation $t^*$ whose $\delta$-neighborhood with respect to the maximum norm contains the most transformation points from random experiments for some parameter $\delta$. Thus, along with the shapes $A$ and $B$ we have two additional input parameters: $N$ determines the number of random experiments and $\delta$ adjusts the clustering size.

This algorithm captures the intuitive notion of matching. Transformations whose $\delta$-neighborhoods contain many “votes” should be “good” translations since they map many points from $A$ onto points from $B$. Figure 1 illustrates this idea for the case of translations.

**Translations.** Observe that two points in the plane uniquely determine a translation that maps one point onto the other. Therefore, a point sample for the case of translations consists of one randomly selected point of each shape.

**PROBMATCH**

**INPUT:** shapes $A$ and $B$, an integer $N$, and a positive real $\delta$.

1. Perform the following experiment $N$ times:
   - Draw uniformly distributed random points $a \in A$ and $b \in B$.
   - Register the translation vector $b-a$.

2. Determine a translation $t^*$ whose $\delta$-neighborhood contains the most registered vectors.

**OUTPUT:** translation $t^*$

**Rigid Motions with Random Angle.** The algorithm for rigid motions, PROBMATCHRMRA, is similar to the algorithm for translations. The space of rigid motions $R$ is given as $I \times \mathbb{R}^2 \subset \mathbb{R}^3$ where $I = [-1/2, 1/2)$. We use the interval $[-1/2, 1/2)$ instead of $[-\pi, \pi)$ because we regard this interval as a probability space, which should have measure 1, avoiding a constant in the density function. A point $(\alpha, t) \in R$ denotes the rigid motion

$$x \mapsto M_\alpha x + t, \quad M_\alpha = \begin{pmatrix} \cos 2\pi \alpha & -\sin 2\pi \alpha \\ \sin 2\pi \alpha & \cos 2\pi \alpha \end{pmatrix}.$$ 

For matching under rigid motions, we select in each step uniformly distributed an angle $\alpha$ and random points $a \in A$ and $b \in B$. We give one “vote” to the unique rigid motion with

---

*In order to make it reasonable to use the same tolerance $\delta$ for both, translations and rotations, it is advisable to normalize the translation space.*

---

Figure 1: We compare two copies of a square under translations. The area of overlap of $t(A)$ and $B$ corresponds to the chance of choosing a point pair $(x, y) \in A \times B$ such that $y - x = t$. 

---
counter-clockwise rotation angle $\alpha$ that maps $a$ onto $b$, namely the map  
$$x \mapsto M_\alpha x + (b - M_\alpha a).$$

**Rigid Motions with $3+1$ Points.** Another variant for rigid motions is the algorithm PROBMATCHRM$3+1$, which does not choose a completely random rotation but prefers directions that are present in the shape. A rigid motion is determined by selecting two points $a_1, a_2$ in $A$ and one point $b_1$ in $B$ uniformly at random. Then, we select another point $b_2$ in $\mathbb{R}^2$ such that the distances between the points in $a_1$ and $a_2$ and $b_1$ and $b_2$ are the same, i.e., $b_2 = b_1 + \|a_2 - a_1\|M_\beta(1)$, where $\beta \in [-1/2, 1/2)$ is randomly selected under uniform distribution. If $b_2$ happens to be in $B$, $(a_1, a_2, b_1, b_2)$ is a valid random sample. Otherwise, we discard the sample and select new points. In this way, we select uniformly distributed tuples from  
$$S = \{(a_1, a_2, b_1, \beta) \in A^2 \times B \times I : b_2 = b_1 + \|a_2 - a_1\|M_\beta(1) \in B\}.$$

**2.2 Main Results**

**Approximation Theorems.** First, we give bounds on the required number of random experiments. The main results are the following approximation theorems.

**Theorem 1** (Absolute Approximation). For any two shapes $A$ and $B$ and parameters $\varepsilon, \tau$ with $0 < \varepsilon, \tau < 1$ there exist a positive real $\delta = \Theta(\varepsilon)$ and an integer $N$ such that the following holds: Let the transformation $t^*$ be the output of PROBMATCHT or PROBMATCHRMRA, respectively, let $t^{\text{opt}}$ be a transformation that maximizes the area of overlap of $A$ and $B$, then  
$$| |t^*(A) \cap B| - |t^{\text{opt}}(A) \cap B| | < \varepsilon|A|$$

with probability at least $1 - \tau$. In the case of translations  
$$N = \mathcal{O}\left(\frac{c}{\varepsilon^6} \log(\max\{1/\tau, c/\varepsilon\})\right),$$

in the case of rigid motions  
$$N = \mathcal{O}\left(\frac{C}{\varepsilon^8} \log(\max\{1/\tau, C/\varepsilon\})\right),$$

where $c = |B|^2 \Delta^4/|A|^4$, $C = |B|^2 \Delta^6 D^6/|A|^6$, $\Delta$ is the length of the boundary of $A$ and $D$ is the diameter of $A$.

If we know that the shapes we have to match are not too “skinny” we can also bound the number of experiments required by algorithm PROBMATCHRM$3+1$ in order to achieve the absolute approximation error of at most $\varepsilon|A|$.

We say that a shape $A$ is $\kappa$-fat\footnote{Our definition of $\kappa$-fatness differs from the standard definition.} for some constant $0 < \kappa \leq 1$ if there exists an inscribed circle $C \subset A$ such that $|C| \geq \kappa|A|$.

**Theorem 2.** Let $A$ and $B$ be two $\kappa$-fat shapes such that the largest inscribed circle in $A$ is at most as large as the largest inscribed circle in $B$. For all parameters $\varepsilon, \tau$ with $0 < \varepsilon, \tau < 1$ there exist a positive real $\delta = \Theta(\varepsilon)$ and an integer $N$ such that the following holds: Let the transformation $t^*$ be the output of PROBMATCHRM$3+1$ and $t^{\text{opt}}$ a transformation that maximizes the area of overlap of $A$ and $B$, then  
$$| |t^*(A) \cap B| - |t^{\text{opt}}(A) \cap B| | < \varepsilon|A|$$

with probability at least $1 - \tau$. The required number of experiments $N$ is  
$$N = \mathcal{O}\left(\max\left\{\frac{C'}{\varepsilon^8\kappa^3} \log\left(\max\left\{\frac{1}{\tau}, \frac{C'}{\varepsilon\kappa}\right\}\right), \frac{1}{\kappa^3} \log\frac{1}{\tau}\right\}\right)$$

where $C' = |B|^2 \Delta^6 D^6/|A|^6$, $\Delta$ is the length of the boundary of $A$ and $D$ is the diameter of $A$. 

|Page Dimensions: 612.0x792.0 |
Further, under the assumption that the shapes are $\kappa$-fat, we get a relative approximation for all three variants of the algorithm from the absolute approximation results. For algorithms $\text{ProbMatchT}$ and $\text{ProbMatchRMRA}$ a weaker assumption that the maximal area of overlap of $A$ and $B$ is at least a constant fraction of $|A|$, i.e., $\max t |t(A) \cap B| \geq \kappa |A|$ for some $0 < \kappa \leq 1$, is sufficient for the relative error bound. Observe that if the two shapes $A$ and $B$ are $\kappa$-fat and $A$ is the shape with the smaller largest inscribed circle, then $\max t |t(A) \cap B| \geq \kappa |A|$.

The relative error bound follows if we choose $\epsilon = \epsilon \kappa$ and apply the absolute approximation results:

$$||t^\text{opt}(A) \cap B| - |t^*(A) \cap B|| \leq \epsilon |A| = \epsilon \kappa |A| \leq \epsilon |t^\text{opt}(A) \cap B|.$$ 

**Corollary 3 (Relative Approximation).** Given two shapes $A$ and $B$, let $t^*$, $t^\text{opt}$, $\epsilon$, $\delta$, $\tau$, $N$ be as in Theorem 1 for algorithms $\text{ProbMatchT}$ and $\text{ProbMatchRMRA}$, and as in Theorem 2 for algorithm $\text{ProbMatchRM3+1}$. Assume that $|t^\text{opt}(A) \cap B| \geq \kappa |A|$ for some constant $\kappa$ in case of translations and rigid motions with random rotation angle. For rigid motions with $3 + 1$ points assume that $A$ and $B$ are $\kappa$-fat. Then with probability at least $1 - \tau$

$$||t^*(A) \cap B| - |t^\text{opt}(A) \cap B|| \leq \epsilon |t^\text{opt}(A) \cap B|$$

if $N$ is chosen as in Theorem 2 for algorithms $\text{ProbMatchT}$ and $\text{ProbMatchRMRA}$, only that now $c = |B|^2 \Delta^4 |A|^4 \kappa^6$ and $C = |B|^2 \Delta^6 B^6 / |A|^6 \kappa^8$, where $\Delta$ is the length of the boundary of $A$ and $D$ is the diameter of $A$. For algorithm $\text{ProbMatchRM3+1}$ the necessary number of experiments is $N = O \left( \max \left\{ \frac{C'}{\epsilon^6 \kappa^{	au}} \log \left( \max \left\{ \frac{1}{\tau}, \frac{C'}{\epsilon^6} \right\} \right), \frac{1}{\epsilon^6 \kappa^{	au}} \log \frac{1}{\tau} \right\} \right)$, where $C'$ is as in Theorem 2.

**Runtime for Sets of Polygons.** The runtime of the algorithm consists of the time $T_{\text{gen}}$ needed to generate $N$ random samples and the time $T_{\text{arr}}$ needed to find the transformation $t^*$ whose $\delta$-neighborhood contains the most registered transformation vectors.

Assume that shapes are sets of polygons, without loss of generality, sets of triangles. A random point in a triangle can be generated in constant time using barycentric coordinates. For generating a random point from a set of $n$ triangles we select a triangle randomly with probability proportional to the relative area of the triangle and then take a random point from the selected triangle. We first compute the areas of the triangles and partition the unit interval $[0,1]$ by subintervals whose lengths are proportional to these areas. Then the selection of a random $a \in [0,1]$ is binary search on this partition gives us a random triangle. Thus, we get preprocessing time linear in $n$ and $O(\log n)$ generation time for a single point. Therefore, $T_{\text{gen}}(n, N) = O(n + N \log n)$.

Determining a translation whose $\delta$-neighborhood obtained the most “votes” can be done by traversing the arrangement $A$ given by the boundaries of the $\delta$-neighborhoods of the $N$ votes from the random experiments. The depth of a cell is defined as the number of neighborhoods it is contained in. The candidates for the output of the algorithm are the transformations contained in the deepest cells in this arrangement because a transformation $t$ lies in the intersection of $k$ of the neighborhoods if and only if its neighborhood contains $k$ votes. The size of the arrangement is $O(N^2)$ for translations and $O(N^3)$ for rigid motions. The deepest cells can be determined by constructing and traversing the complete arrangement, which can be accomplished in time $O(N^2)$ for translations and $O(N^3)$ for rigid motions.

The runtime can be improved if, instead of the deepest cell in the arrangement, an approximately deepest cell is computed. If the depth of the arrangement is $d$, a witness point of depth $k$ such that $(1 - \epsilon) d \leq k \leq d$ can be computed in time $T_{\text{arr}}(N) = O(N \epsilon^{-2} \log N)$ 2. The total runtime of the algorithm is then $O(N \epsilon^{-2} \log N + N \log n + n)$. We will show later that the quality of the output can still be guaranteed if we approximate the depth.

In the following theorem we refer to the probabilistic algorithms as described in Section 2.1 except that in step 2 of each algorithm a transformation with an approximately largest number of “votes” in its $\delta$-neighborhood is returned.

**Theorem 4.** Let $A$ and $B$ be two shapes represented by sets of $n$ triangles in total. Let $t^\text{opt}$ denote the transformation maximizing the area of overlap of $A$ and $B$ For a given error tolerance
Theorem 5.

Example [9].

Probability theoretical transformation formula for density functions of random variables, see for induced density function is proportional to the squared area of overlap. Additionally, we show that for rigid motions with random rotation angle the value of the density function for a transformation is proportional to the area of overlap for rigid motions with random rotation angle the value of the density function for a transformation.

In this section, we analyze the density functions of the probability distribution induced by the random experiment. It turns out that in the case of translations and in the case of rigid motions, where the rotation angle is chosen randomly, the density function is proportional to the length of the boundary of A and D is the diameter of A.

For algorithm ProbMatchRM3+1 the shapes A and B are additionally required to be κ-fat for some $0 < \kappa \leq 1$. The running time of the algorithm is then $O\left(\max\left\{ \frac{C'}{\varepsilon^2 \kappa^4} \log \left( \max \left\{ \frac{1}{\varepsilon^2}, \frac{C'}{\kappa^2} \right\} \right), \frac{1}{\varepsilon^2} \log \frac{1}{\varepsilon^2} \right\} \right)$, where $C' = |B|^2 \Delta^6 D^6 / |A|^6$.

2.3 Overview of the Analysis

In Section 3, we analyze the probability distribution implicitly given in the transformation space by the random experiment. It turns out that in the case of translations and in the case of rigid motions where the rotation angle is chosen randomly, the density function is proportional to the length of the boundary of A and D is the diameter of A. For algorithm ProbMatchRM3+1 the shapes A and B are additionally required to be κ-fat for some $0 < \kappa \leq 1$. The running time of the algorithm is then $O\left(\max\left\{ \frac{C'}{\varepsilon^2 \kappa^4} \log \left( \max \left\{ \frac{1}{\varepsilon^2}, \frac{C'}{\kappa^2} \right\} \right), \frac{1}{\varepsilon^2} \log \frac{1}{\varepsilon^2} \right\} \right)$, where $C' = |B|^2 \Delta^6 D^6 / |A|^6$.

3 Density Functions

3.1 Determining the Density Functions

In this section, we analyze the density functions of the probability distribution induced by the random experiments of the algorithm in the transformation space. We show that for translations and for rigid motions with random rotation angle, the value of the density function for a transformation is proportional to the area of overlap $|\tau(A) \cap B|$. For the algorithm ProbMatchRM3+1 the induced density function is proportional to the squared area of overlap. Additionally, we show that in all three cases the density functions are Lipschitz continuous.

For deriving the density functions underlying the random experiments, we will use the following probability theoretical transformation formula for density functions of random variables, see for example [9].

Theorem 5. Let $X : \mathbb{R}^n \to \mathbb{R}^n$ be a random variable with density function $f_X$, open set $G \subset \mathbb{R}^n$ be the support of $f_X$ and $\varphi : G \to \mathbb{R}^n$ a continuously differentiable injective map, i.e., $\varphi : G \to G'$, where $G' = \varphi(G)$, is a bijection. Let $\Delta(x) = \det(\frac{\partial \varphi}{\partial x}(x))_{i,j=1,...,n}$. Then $\varphi \circ X$ has the density function

$$f_{\varphi \circ X}(y) = \begin{cases} f_X(\varphi^{-1}(y)) |\Delta(\varphi^{-1}(y))|^{-1} & \text{for } y \in G' \\ 0 & \text{for } y \notin G' \end{cases}.$$
For translations and rigid motions with random rotation angle we can apply the following special case:

**Corollary 6.** Let \( X : \mathbb{R}^n \to \mathbb{R}^n \) be a random variable with density function \( f_X \) and \( h : \mathbb{R}^n \to \mathbb{R}^n \), \( h : x \mapsto Mx \) a linear map with \( \det(M) \neq 0 \). Then \( h \circ X \) has the density function
\[
f_{h \circ X}(y) = f_X(M^{-1}y) \, |\det(M^{-1})|.
\]

For a subset \( B \) of a set \( R \) let \( \chi_B : R \to \{0,1\} \) be the characteristic function of \( B \) that is 1 if a point from \( R \) is in \( B \) and 0 otherwise.

**The Density Function for Translations.**

**Lemma 7 (Translations).** The density function of the probability distribution on the translation space that results from the experiment in algorithm PROBMATCHTRANS is given by
\[
g_T(t) = |t(A) \cap B|/(|A||B|).
\]

**Proof.** We model the experiment by regarding \( R \) point from \( \text{Lemma 7} \). The Density Function forTranslations. We model the experiment by regarding \( R \) point from \( \text{Lemma 8} \). The density function on the translation space to the last two coordinates:

Consider the bijective function \( \varphi : \mathbb{R}^4 \to \mathbb{R}^4 \), \( \varphi : (a, b) \mapsto (a, b - a) \). \( \varphi \) maps a pair of points \((a, b)\) to a point-translation pair \((a, t)\) where \( t \) is the translation that maps \( a \) to \( b \). By Corollary 6 the density function of \( \varphi \circ X \) is
\[
f_{\varphi \circ X}(a, t) = \frac{\chi_A(a) \chi_B(a + t)}{|A||B|} = \frac{\chi_{A \cap (B - t)}(a)}{|A||B|}.
\]

The density function on the translation space \( \mathbb{R}^2 \) is the density function of the projection of \( \varphi \circ X \) to the last two coordinates:
\[
g_T(t) = \int_{a \in \mathbb{R}^2} f_{\varphi \circ X}(a, t) \, da = \frac{|A \cap (B - t)|}{|A||B|} = \frac{|t(A) \cap B|}{|A||B|}.
\]

**The Density Function for Rigid Motions with Random Angle.**

**Lemma 8 (Rigid Motions with Random Angle).** The density function on the space of rigid motions \( R \) induced by algorithm PROBMATCHRMRA is given by
\[
g_{RA}(r) = |r(A) \cap B|/(|A||B|).
\]

**Proof.** Our random experiment consists in selecting uniformly distributed points from \( \Omega = I \times A \times B \) where \( I = [-1/2, 1/2] \). We are interested in the density function \( f_Y \) of the random variable
\[
Y : \Omega \to R, \quad Y : (\alpha, a, b) \mapsto (\alpha, b - M_\alpha a).
\]

We will express the density function of \( Y \) in terms of the conditional probability densities of the following two random variables \( Y_I \) and \( Y_T \) defined as
\[
Y_I : \Omega \to I, \quad Y_I : (\alpha, a, b) \mapsto \alpha,
\]
\[
Y_T : \Omega \to \mathbb{R}^2, \quad Y_T : (\alpha, a, b) \mapsto b - M_\alpha a.
\]

The density function of \( Y \) is the joint density of the random variables \( Y_I \) and \( Y_T \). Recall that the counterclockwise rotation angle is selected uniformly distributed in \( I \) independently from the
The conditional probability density can also be expressed in terms of the joint probability density $f_T(t \mid Y_I = \alpha) = \frac{|(M_{\alpha}A + t) \cap B|}{|A||B|}$.

The conditional probability density can also be expressed in terms of the joint probability density $f_T(t \mid Y_I = \alpha) = f_Y(\alpha, t)/f_I(\alpha)$. Thus we get for any rigid motion $r = (\alpha, t)$ that

$$g_{RA}(r) = f_Y(r) = |r(A) \cap B|/(|A||B|)$$.

**Lemma 9** (Rigid Motions with 3+1 Points). The density function on the space of rigid motions $R$ induced by the algorithm PROBMATCHRM3+1 is given by

$$g_{3+1}(r) = |r(A) \cap B|^2/c$$,

where $c$ is a positive real depending on $A$ and $B$ which is at most $|A|^2|B|$.

**Proof.** In one random experiment we select uniformly distributed random elements from the set

$$S = \{(a_1, a_2, b_1, \beta) \in A^2 \times B \times I : a_1 \neq a_2, b_2 = b_1 + \|a_2 - a_1\| M_{\beta}(I_a) \in B\}$$.

The density function of the random variable $X = id_S$ is then

$$f_X(a_1, a_2, b_1, \beta) = \frac{\chi_S(a_1, a_2, b_1, \beta)}{|S|} = \frac{\chi_A(a_1) \chi_A(a_2) \chi_B(b_1) \chi_B(b_2)}{|S|}$$,

where $b_2$ is as in the definition of $S$.

Let $Y$ denote the random variable corresponding to the rigid motion resulting from one random experiment:

$$Y : S \rightarrow R, \quad Y : (a_1, a_2, b_1, \beta) \mapsto (\alpha, b_1 - M_{\alpha}a_1)$$,

where $\alpha = \angle(a_2 - a_1, b_2 - b_1)/2\pi$. We represent $Y$ as a composite function of random variable $X$. Define functions $\varphi_1, \varphi_2$ as follows:

$$\varphi_1 : S \rightarrow \mathbb{R}^6 \times I \quad \varphi_1 : (a_1, a_2, b_1, \beta) \mapsto (a_1, a_2, b_1 - M_{\alpha}a_1, \alpha)$$

$$\varphi_2 : \mathbb{R}^6 \times I \rightarrow R \quad \varphi_2 : (a_1, a_2, t, \alpha) \mapsto (\alpha, t)$$.

Then $Y = \varphi_2 \circ \varphi_1 \circ X$.

Observe that the set $S$ is open, since the sets $A$ and $B$ are open, the excluded set of tuples where $a_1 = a_2$ is a closed set, and the interval $I$ is equivalent to a unit circle and is therefore open. Further, the function $\varphi_1$ and its inverse are bijective and differentiable, so we can apply Theorem 1 to $\varphi_1 \circ X$. We first compute the determinant $\Delta(x)$ of the Jacobian matrix of $\varphi_1$. It is easy to see that $\det(\frac{\partial \varphi_1}{\partial x_j})_{i,j=1,\ldots,7} = \det(\frac{\partial \varphi_1}{\partial x_j})_{i,j=5,\ldots,7}$ since $\varphi_1(x_1, \ldots, x_7) = x_i$ for $i = 1, \ldots, 4$.

Note that the angle $\alpha$ does not depend on $b_1$ and it depends linearly on $\beta$: $\alpha = \beta - \gamma$, where
\[ \gamma = \angle(a_2 - a_1, \langle \rangle)/2\pi. \] Therefore, \( \frac{\partial (b_i - Ma)_{ij}}{\partial b_{ij}} = \delta_{ij}, \frac{\partial a}{\partial b_{ij}} = 0 \) for \( j = 1, 2, \) and \( \frac{\partial b}{\partial y} = 1. \) Now we have that
\[ \left( \frac{\partial \varphi_i}{\partial x_j} \right)_{i,j=5,\ldots,7} = \begin{pmatrix} 1 & 0 & \lambda_1 \\ 0 & 1 & \lambda_2 \\ 0 & 0 & 1 \end{pmatrix}, \]
for some \( \lambda_1, \lambda_2 \in \mathbb{R}. \) Thus, \( \Delta(x) = 1. \) The inverse function of \( \varphi_1 \) maps a tuple \((a_1, a_2, t, \alpha)\) to \((a_1, a_2, t + Ma, a_1, \alpha + \gamma).\) By Theorem 5 we get that the density function of \( \varphi_1 \circ X \) is
\[ f_{\varphi \circ \delta} (a_1, a_2, t, \alpha) = \chi_A(a_1) \chi_A(a_2) \chi_B(t + Ma_1) \chi_B(t + Ma_2)/|S| \]
\[ = \chi_A(a_1) \chi_A(a_2) \chi_{M^{-\alpha}(B-t)}(a_1) \chi_{M^{-\alpha}(B-t)}(a_2)/|S|. \]

The density function of random variable \( Y \) on \( R \) is then
\[ g_{3+1}(\alpha, t) = 1/|S| \int_{A^2} \chi_{(A \cap r^{-1}(B))^2} (a_1, a_2) \, d(a_1, a_2) \]
\[ = |A \cap r^{-1}(B)|^2/|S| \]
\[ = |r(A) \cap B|^2/|S|, \]
where \( r = (\alpha, t). \)

### 3.2 Lipschitz Continuity of the Density Functions.

In this section we show that the density functions of the probability distribution induced in the space of transformations by the algorithm are Lipschitz continuous.

A function \( h \) from a metric space \( M \) to \( \mathbb{R} \) is called Lipschitz continuous if there is a constant \( L \) such that for all \( x, y \in M \) holds
\[ ||x - y|| < \delta \implies |h(x) - h(y)| < L \delta. \]

Let \( B_t^\delta \) denote the \( \delta \)-neighborhood of a transformation \( t \) with respect to the maximum norm and let \( \mu_\delta \) be the Lebesgue measure of \( B_t^\delta \). We are interested in the density functions to be Lipschitz continuous because then \( P(B_t^\delta)/\mu_\delta \) converges to \( h(t) \) for \( \delta \to 0 \) uniformly on the transformation space, where \( P \) is the probability distribution with density function \( h \).

**Lemma 10.** For fixed shapes \( A \) and \( B \) let \( h \) be the density function of the probability distribution \( P \) in the transformation space induced by the probabilistic algorithm. There exists a constant \( L \) such that for every transformation \( t \)
\[ |P(B_t^\delta) - \mu_\delta h(t)| \leq L \mu_\delta \delta, \]
where \( B_t^\delta \) denotes the \( \delta \)-neighborhood of a transformation \( t \) with respect to the maximum norm and \( \mu_\delta \) is the Lebesgue measure of \( B_t^\delta \).

For translations \( L = L_T = \sqrt{2} \Delta/|A||B|, \) for rigid motions and algorithm \( \text{ProbMatchRMRA} \)
\[ L = L_{RA} = (\sqrt{2} + 2\pi D) \Delta/|A||B|, \] and for rigid motions and algorithm \( \text{ProbMatchRM3+1} \)
\[ L = L_{3+1} = 2(\sqrt{2} + 2\pi D) \Delta \min(|A|, |B|)/c, \] where \( D \) is the diameter and \( \Delta \) the boundary length of \( A, \) and \( c \) is the constant from Lemma 4.

**Proof.** Assume that \( h \) is Lipschitz continuous with constant \( L \) then
\[ P(B_t^\delta) = \int_{B_t^\delta} h(x) \, dx \leq \mu_\delta \sup_{x \in B_t^\delta} h(x) \leq \mu_\delta (h(t) + L \delta) \] and
\[ \int_{B_t^\delta} h(x) \, dx \geq \mu_\delta \inf_{x \in B_t^\delta} h(x) \geq \mu_\delta (h(t) - L \delta). \]

It remains to show that for every variant of the probabilistic algorithm the induced probability density function is Lipschitz continuous. Let \( f(r) \) denote the area of overlap \( r(A) \cap B \) for a rigid
motion \( r \). We first show that the function \( f \) is Lipschitz continuous. We assume without loss of generality that the input shapes \( A \) and \( B \) contain the origin.

Let \( r = (\alpha, p), s = (\beta, q) \) be rigid motions whose distance is less than \( \delta \) in the maximum norm. Then the distance between translation vectors is \(|p-q| \leq \sqrt{2}\delta \) and \(|\alpha-\beta| \leq \delta \).

The difference in the area of overlap for \( r \) and \( s \) can be bounded by the area of the symmetric difference between \( r(A) \) and \( s(A) \):

\[
f(r) = |r(A) \cap B| = |(r(A) \setminus s(A)) \cap B| + |(r(A) \cap s(A)) \setminus B|
\leq |r(A) \setminus s(A)| + |s(A) \setminus r(A)|.
\]

Thus, \( f(r) - f(s) \leq |r(A) \setminus s(A)|. \) Similarly, \( f(s) - f(r) \leq |s(A) \setminus r(A)|. \) Combining these two estimates we get

\[
|f(r) - f(s)| \leq \max(|r(A) \setminus s(A)|, |s(A) \setminus r(A)|).
\]

Let \( w(\delta) \) be the maximal length of the line segment \( \overline{r(x)s(x)} \) for \( x \in A \). The difference in the area of overlap is at most \( \Delta w(\delta) \) since \( r(A) \) and \( s(A) \) differ by at most a \( w(\delta) \)-wide strip along the boundary of \( r(A) \). Next we find an upper bound on the length \( w(\delta) \).

By an easy geometric argument the distance between a point \( x \) and its rotated image can be expressed as \(|x - M_\alpha x| = 2|x| \cdot \sin(2\alpha/2)|\) for \( 0 \leq 2\pi\alpha \leq \pi/2 \). Since \(|\sin \gamma| \leq |\gamma| \) for all \( \gamma \) this distance can be bounded by \(|x - M_\alpha x| \leq |x| \cdot |2\pi\alpha| \).

Let \( x \in A \) then \(|x| \leq D \). We use the above argument to bound the distance between the image of \( x \) under rigid motions \( r \) and \( s \). Observe that since \( \delta \) is small we can assume that \( 0 \leq |2\pi\delta| \leq \pi/2 \).

\[
||r(x) - s(x)|| = ||M_\alpha x + p - M_\beta x - q||
\leq ||M_\alpha x - M_\beta x|| + ||p - q||
\leq ||M_{\alpha-\beta} x|| + \sqrt{2}\delta
\leq 2|\alpha - \beta| \cdot |x| + \sqrt{2}\delta
\leq 2\pi\delta D + \sqrt{2}\delta = (\sqrt{2} + 2\pi D)\delta
\]

for all \( x \in A \).

Then for arbitrary rigid motions \( r \) and \( s \) such that \( ||r - s|| < \delta \) the difference in the area of overlap can be bounded by \(|f(r) - f(s)| \leq (\sqrt{2} + 2\pi D)\delta \Delta \). The Lipschitz constant for the area of overlap is then \( L_f = (\sqrt{2} + 2\pi D)\Delta \).

The density function of the probability distribution in the space of rigid motions induced by the algorithm PROBMATCHRMRA is \( g_{RA}(r) = f(r)/(|A||B|) \) by Lemma 8. Then for rigid motions \( r \) and \( s \) such that \( ||r - s|| < \delta \) we get

\[
|g_{RA}(r) - g_{RA}(s)| = |f(r) - f(s)|/(|A||B|) < (\sqrt{2} + 2\pi D)\Delta \delta/(|A||B|).
\]

Thus, the Lipschitz constant of the function \( g_{RA} \) is \( L_{RA} = (\sqrt{2} + 2\pi D)\Delta/(|A||B|) \).

The density function induced by the algorithm PROBMATCHRM3+1 is \( g_{3+1}(r) = f^2(r)/c \), where \( c \) is the constant from Lemma 8.

Observe that if \( f \) is bounded and Lipschitz continuous with Lipschitz constant \( L_f \), then \( f^2 \) is also Lipschitz continuous with constant \( L_{f^2} = 2L_f \sup_x f(x) \) due to the following consideration:

\[
|f^2(x) - f^2(y)| = |f(x) - f(y)| \cdot |f(x) + f(y)| < L_f \cdot |x - y| \cdot |f(x) + f(y)|
\leq 2L_f |x - y| \sup_z f(z)
= 2(\sqrt{2} + 2\pi D)\Delta |x - y| \sup_z f(z)/c.
\]

Thus, the Lipschitz constant of the function \( g_{3+1} \) is

\[
L_{3+1} = 2(\sqrt{2} + 2\pi D)\Delta \sup_z f(z)/c.
\]
The maximal possible area of overlap of two shapes under rigid motions is clearly bounded by the area of the smaller shape. Therefore, the function $g_{3+1}$ is Lipschitz continuous with constant $L_{3+1} \leq 2(\sqrt{2} + 2\pi D)\Delta \min(|A|,|B|)/c$.

In the case of translations we can disregard rotation, so the Lipschitz constant $L_{RA} = (\sqrt{2} + 2\pi D)\Delta/(|A||B|)$ for the density function in the case of rigid motions reduces to $L_T = \sqrt{2}\Delta/(|A||B|)$ for translations.

Note that the constants depend heavily on the shapes. \hfill \Box

### 4 Absolute Error Approximation

In the previous section (Lemma 10) we showed that for the probability distributions in the space of transformations induced by the algorithms for translations and for rigid motions the value of the probability function $P$ for a $\delta$-neighborhood $B_\delta^t$ (divided by the measure $\mu_\delta$ of the $\delta$-neighborhood) of a transformation $t$ converges to the value of the density function $h(t)$ for that transformation as $\delta$ approaches zero.

In this section we prove that the relative number of “votes” in the $\delta$-neighborhood of a transformation $t$ is a good approximation of the probability $P(B_\delta^t)$ and complete the proofs of Theorem 1 and Theorem 4.

Let the random variable $X_\delta^t(t)$ denote the number of registered transformations in the $\delta$-neighborhood of transformation $t$. We use the Chernoff bound formulated as in \cite{6} for proving that for fixed $t$ with high probability $X_\delta^t(t)/N$ and $P(B_\delta^t)$ do not differ much for large $N$.

**Theorem 11 (Chernoff bound).** Let $X_1, \ldots, X_N$ be independent binary random variables, let $X = \sum_{i=1}^N X_i$, and let $0 < \varepsilon < 1$. Then

$$P(|X - E(X)| > \varepsilon N) < 2e^{-\varepsilon^2 N/2}.$$

Applying this bound to our setting yields

**Corollary 12.** For each transformation $t$ and for all $0 < \varepsilon < 1$

$$P(|X_\delta^t(t)/N - P(B_\delta^t)| > \varepsilon) < 2e^{-\varepsilon^2 N/2}.$$

**Proof.** Define $X_i = \chi_{B_\delta^t_i}$ for $i = 1, \ldots, N$. The $X_i$ are identically distributed, independent, binary random variables with $X_\delta^t(t) = \sum_{i=1}^N X_i$ and $E(X_\delta^t(t)) = NP(B_\delta^t)$. The inequality of Corollary 12 results from applying the Chernoff bound to $X_1, \ldots, X_N$. \hfill \Box

This shows that $X_\delta^t(t)/N$ converges to $P(B_\delta^t)$ in probability as the number of random experiments goes to infinity for each $t$ in the transformation space.

We have already seen that for fixed $t$

$$X_\delta^t(t)/N \xrightarrow{\text{in prob.}} \frac{N}{\delta} \quad P(B_\delta^t) \xrightarrow{\delta \to 0} \mu_\delta h(t).$$

Now we need to analyze what happens if the transformation vector is determined by the sequence of random experiments, namely a vector whose $\delta$-neighborhood obtains the most “votes”, and thus is a random vector itself.

The output of the algorithm can be modeled as a random variable

$$Z_N^\delta = \max_t X_\delta^t(t).$$

Let $S = (s_1, \ldots, s_N)$ be a sequence of transformations from the random experiments. Consider the arrangement $\mathcal{A}$ induced by the boundaries of $B_\delta^{s_1}, \ldots, B_\delta^{s_N}$, which are the $\delta$-spheres with respect to the maximum norm of the points in $S$. The depth of a cell is defined as the number of $B_\delta^{s_t}$ it is
contained in. The candidates for the output of the algorithm are the transformations contained in the deepest cells in this arrangement. A transformation \( t \) lies in the intersection of \( k \) of the neighborhoods if and only if its neighborhood contains \( k \) “votes”.

The next lemma can be proven using an idea of [6].

**Lemma 13 (Key Lemma).** Let \( V \) be the set of all vertices of the arrangement \( \mathcal{A} \) and \( t^{\text{opt}} \) the transformation maximizing the area of overlap \( |t(A) \cap B| \). Then for each \( \varepsilon > 0 \) and \( N > 6/\varepsilon + 2 \) holds in the case of translations

\[
P(\exists t \in V \cup \{t^{\text{opt}}\} : |X^t_N(t)/N - P(B^t_0)| > \varepsilon) < 2N^2e^{-\varepsilon^2(N-2)/8};
\]

and in the case of rigid motions,

\[
P(\exists t \in V \cup \{t^{\text{opt}}\} : |X^t_N(t)/N - P(B^t_0)| > \varepsilon) < \frac{2}{3}N^3e^{-\varepsilon^2(N-3)/8}.
\]

**Proof.** In the case of translations, a vertex of \( \mathcal{A} \) is defined by 2 \( \delta \)-spheres, and 2 \( \delta \)-spheres define at most 2 vertices, so \( |V| \leq N(N-1) \) and \( |V \cup \{t^{\text{opt}}\}| \leq N^2 \). In the case of rigid motions, a vertex of \( \mathcal{A} \) is defined by 3 \( \delta \)-spheres, and 3 \( \delta \)-spheres define at most 2 vertices, so \( |V| \leq 2(N^3/3) = N^3 - 2N + 2N/3 \) and \( |V \cup \{t^{\text{opt}}\}| \leq N^3/3 \).

Let us consider translations first. Let \( t \) be a vertex of \( \mathcal{A} \), then \( t \) is an intersection point of two \( \delta \)-spheres \( B^v_0, B^v_0 \) for some votes \( v, w \). Consider same random sequence without two experiments yielding \( v \) and \( w \). Since the random points are independent and the choice of \( t \) does not depend on the shorter random sequence, we can apply Corollary 12 to \( t \) with \( N - 2 \) experiments.

\[
P(|X^t_N(t)/N - P(B^t_0)| > \varepsilon/2) < 2e^{-\varepsilon^2(N-2)/8}.
\]

For each \( \delta \)-neighborhood, the fractions of “votes” that lie in the neighborhood differ by at most \( 2/(N - 2) \) if two arbitrary “votes” are deleted. Therefore,

\[
|X^t_N(t)/N - P(B^t_0)| \leq |X^t_{N-2}(t)/(N - 2) - P(B^t_0)| + 2/(N - 2).
\]

Choosing \( N \geq 4/\varepsilon + 2 \) we get that \( 2/(N - 2) \leq \varepsilon/2 \) and

\[
P(|X^t_N(t)/(N) - P(B^t_0)| > \varepsilon) < 2e^{-\varepsilon^2(N-2)/8}.
\]

As argued above there are at most \( N^2 \) such vertex points together with the point \( t^{\text{opt}} \). Applying the triangle inequality we get the claim of the Lemma for the case of translation.

The argumentation for rigid motions is analogous.

Next we show that if the probability density function \( h \) is Lipschitz continuous then the value of \( P(B^t_0) \) for two transformations that lie in one \( \delta \)-neighborhood does not differ much.

**Proposition 14.** Let \( r, s, t \) be transformations such that \( r, s \in B^t_0 \). Then

\[
|P(B^r_0) - P(B^s_0)| < 4L\mu_3\delta
\]

where \( L \) is the Lipschitz constant of the density function \( h \) of \( P \) and \( \mu_3 \) is the Lebesgue measure of a \( B^t_0 \).

**Proof.**

\[
|P(B^r_0) - P(B^s_0)| = \left| \int_{B^t_0} h(v)dv - \int_{B^t_0} h(v)dv \right| \leq \mu_3(\sup_{B^t_0} h(v) - \inf_{B^t_0} h(v))
\]

\[
< 4L\mu_3\delta.
\]

It follows from Lemma 13 and Proposition 14 that with high probability for every transformation \( t \) the relative number of votes in its \( \delta \)-neighborhood is a good approximation of the probability \( P(B^t_0) \).
Corollary 15. Let $0 < \varepsilon < 1$ and $N \geq N_{\varepsilon}/(N_{\varepsilon}+2)$. For all transformations $t$ with probability at least $1 - 2N_{\varepsilon}e^{-\varepsilon^2(N_{\varepsilon}-2)/8}$ in the case of translations and with probability at least $1 - \frac{1}{8}3N_{\varepsilon}e^{-\varepsilon^2(N_{\varepsilon}-3)/8}$ in the case of rigid motions it holds

$$|X_{N_{\varepsilon}}(t)/N - P(B_{\varepsilon})| < \varepsilon + 4L\mu_{\delta},$$

where $L$ is the Lipschitz constant of the probability density function.

Proof. Let $t$ be an arbitrary transformation and let $t'$ be a vertex of the cell in $A$ which contains $t$, such that $X_{N_{\varepsilon}}(t') = X_{N_{\varepsilon}}(t)$. Then

$$|X_{N_{\varepsilon}}(t) - P(B_{\varepsilon})| \leq |X_{N_{\varepsilon}}(t') - P(B_{\varepsilon})| + |P(B_{\varepsilon}) - P(B_{\varepsilon})|$$

$$\leq \varepsilon + 4L\delta\mu_{\delta} \quad \text{by Lemma 13 and Proposition 14} .$$

That means that the output of the algorithm does not need to be chosen among the vertices of the arrangement $A$.

Next we show that if the probability density function is Lipschitz continuous then the transformation with the maximum number of “votes” in its $\delta$-neighborhood results in a good approximation of the maximum of the density function with high probability.

Lemma 16. Let $h(t)$ be the density of the probability distribution $P$ in the transformation space induced by the algorithm, and $L$ the Lipschitz constant of $h$. Let $t^{\text{opt}}$ be the transformation maximizing $h(t)$ and $t^*$ the transformation maximizing $X_{N_{\varepsilon}}(t)$, where $X_{N_{\varepsilon}}(t)$ denotes the number of transformations generated by the random experiments that are contained in the $\delta$-neighborhood of $t$. The Lebesgue measure of a $\delta$-neighborhood is denoted by $\mu_{\delta}$. Then for all $0 < \varepsilon \leq 1$

$$h(t^*) \geq h(t^{\text{opt}}) - 2\varepsilon/\mu_{\delta} - 6L\delta$$

with probability at least $1 - q$, where $q = 2N_{\varepsilon}e^{-\varepsilon^2(N_{\varepsilon}-2)/8}$ for translations and $q = \frac{1}{8}3N_{\varepsilon}e^{-\varepsilon^2(N_{\varepsilon}-3)/8}$ in the case of rigid motions.

Proof. It follows from Lemmas 10 and 13 and from Corollary 15 that with probability at least $1 - q$ the following two statements are true:

$$|\mu_{\delta}h(t^*) - X_{N_{\varepsilon}}(t^*)/N| \leq |\mu_{\delta}h(t^*) - P(B_{\varepsilon})| + |P(B_{\varepsilon}) - X_{N_{\varepsilon}}(t^*)/N|$$

$$\leq L\delta\mu_{\delta} + \varepsilon + 4L\mu_{\delta}\delta \quad \text{by Lemma 10 and Corollary 15}$$

and

$$|\mu_{\delta}h(t^{\text{opt}}) - X_{N_{\varepsilon}}(t^{\text{opt}})/N| \leq |\mu_{\delta}h(t^{\text{opt}}) - P(B_{\varepsilon})| + |P(B_{\varepsilon}) - X_{N_{\varepsilon}}(t^{\text{opt}})/N|$$

$$\leq L\mu_{\delta}\delta + \varepsilon \quad \text{by Lemmas 10 and 13} .$$

By the definition of $t^*$, $X_{N_{\varepsilon}}(t^*) \geq X_{N_{\varepsilon}}(t^{\text{opt}})$. Then

$$h(t^*) \geq (X_{N_{\varepsilon}}(t^*) - \varepsilon - 5L\mu_{\delta})/\mu_{\delta}$$

$$\geq (X_{N_{\varepsilon}}(t^{\text{opt}}) - \varepsilon - 5L\mu_{\delta})/\mu_{\delta}$$

$$\geq (\mu_{\delta}h(t^{\text{opt}}) - \varepsilon - L\mu_{\delta}\delta - \varepsilon - 5L\mu_{\delta}\delta)/\mu_{\delta}$$

$$= h(t^{\text{opt}}) - 2\varepsilon/\mu_{\delta} - 6L\delta ,$$

which concludes the proof. \(\Box\)

Now we can prove Theorem 1.
Proof of Theorem 1. Let \( f(t) \) denote the area of overlap \( t(A) \cap B \), \( h(t) \) the density of the probability distribution \( P \) in the transformation space induced by the algorithm, and \( L \) the Lipschitz constant of \( h \). We will use two parameters \( 0 < \delta, \eta \leq 1 \), which will be determined later. The parameter \( \delta \) specifies the size of the neighborhoods used by the matching algorithms, and \( \eta \) is the error tolerance value used when applying lemmas or corollaries.

Recall that \( t^* \) is a transformation with the maximum number of transformations generated by the random experiments in its \( \delta \)-neighborhood and \( t^{\text{opt}} \) the transformation maximizing \( f(t) \). Let \( q \) denote the failure probability from Lemma 13 in terms of the number of experiments \( N \) and the error tolerance \( \eta \), for translations \( q = 2N^2e^{-\eta^2(N-2)/8} \) and for rigid motions \( q = \frac{2}{3}N^3e^{-\eta^2(N-3)/8} \).

Since \( |t^*(A) \cap B| \leq |t^{\text{opt}}(A) \cap B| \) holds by definition, we only have to show that \( |t^*(A) \cap B| \geq |t^{\text{opt}}(A) \cap B| - \varepsilon|A| \). By Lemma 16 for translations and rigid motions

\[
\begin{align*}
  h(t^*) &\geq h(t^{\text{opt}}) - 2\eta/\mu_\delta - 6L\delta & (2)
\end{align*}
\]

with probability at least \( 1-q \).

Translations: In the case of translations we have by Lemma 7 \( h(t) = |t(A) \cap B|/|A||B| = f(t)/|A||B| \) by Lemma 10 and \( \mu_\delta = 4\delta^2 \). Then by (2)

\[
\begin{align*}
  f(t^{\text{opt}}) - f(t^*) &\leq \frac{2\eta|A||B|}{4\delta^2} + 6\sqrt{2}\delta \Delta .
\end{align*}
\]

Bounding this error to be at most \( \varepsilon|A| \), we get

\[
\eta \leq \frac{4\delta^2\varepsilon|A|}{2|A||B|} - \frac{24\sqrt{2}\delta^3\Delta}{2|A||B|} .
\]

In order to maximize this expression we differentiate it with respect to \( \delta \) and determine the value of \( \delta \) for which that derivative is zero. The value of \( \delta \) maximizing the above expression and the corresponding value of \( \eta \) are then

\[
\begin{align*}
  \delta &= \frac{\varepsilon|A|}{9\sqrt{2}\Delta} & \text{and} & & \eta &= \frac{\varepsilon^3|A|^2}{243\Delta^2|B|} . & (3)
\end{align*}
\]

Finally, we want the probability of failure \( q = 2N^2e^{-\eta^2(N-2)/8} \) to be at most \( \tau \). A straightforward analysis shows that for \( N \geq 80/\eta^2\log(80/\eta^2) \) this value is at most \( e^{-\eta^2(N-2)/16} \). Solving the inequality \( e^{-\eta^2(N-2)/16} \leq \tau \) with respect to \( N \) we get that for \( N \geq \max\{-16/\eta^2\log(1/\tau) + 2, 80/\eta^2\log(80/\eta^2)\} \) the approximation error is at most \( \varepsilon|A| \) with probability at least \( 1-\tau \).

Rigid motions with random rotation angle: Here we have by Lemma 8 \( h(t) = |t(A) \cap B|/|A||B| = f(t)/|A||B| \), \( L = (\sqrt{2} + 2\pi D)\Delta/|A||B| \) by Lemma 10 and \( \mu_\delta = 8\delta^3 \). Then by (2)

\[
\begin{align*}
  f(t^{\text{opt}}) - f(t^{\text{opt}}) &\leq \frac{2\eta|A||B|}{8\delta^3} + 6(\sqrt{2} + 2\pi D)\Delta \delta .
\end{align*}
\]

Again, bounding this error by \( \varepsilon|A| \) and maximizing the expression for \( \eta \) as in the case of translations we get that the optimal choice for \( \delta \) and \( \eta \) is

\[
\begin{align*}
  \delta &= \frac{\varepsilon|A|}{8(\sqrt{2} + 2\pi D)\Delta} & \text{and} & & \eta &= \frac{\varepsilon^4|A|^3}{512(\sqrt{2} + 2\pi D)^3\Delta^3|B|} . & (4)
\end{align*}
\]

By a straightforward analysis the probability of failure \( q = \frac{2}{3}N^3e^{-\eta^2(N-3)/8} \) is at most \( e^{-\eta^2(N-2)/16} \) for all \( N \geq 112/\eta^2\log(112/\eta^2) \). Solving the inequality \( e^{-\eta^2(N-2)/16} \leq \tau \) with respect to \( N \) we get that for all \( N \geq \max\{-16/\eta^2\log(1/\tau) + 3, 112/\eta^2\log(112/\eta^2)\} \) the approximation error of the algorithm is at most \( \varepsilon|A| \) with probability at least \( 1-\tau \). \( \square \)

Next we prove Theorem 2 in a similar fashion.
Proof of Theorem 2. Since in algorithm PROBMATCHRM3+1 some random samples are rejected and, therefore, do not induce a vote in the transformation space, we first determine the necessary number of not rejected experiments, in the following denoted by \( M \), in order to guarantee the required error bound with high probability. Afterwards, we determine the total number \( N \) of random samples that the algorithm needs to generate in order to record at least \( M \) votes in the transformation space with high probability.

Let \( f(t) \) denote the area of overlap \( t(A) \cap B \), \( h(t) \) the density of the probability distribution \( P \) in the space of rigid motions induced by algorithm PROBMATCHRM3+1, and \( L \) the Lipschitz constant of \( h \).

Let \( t^* \) be a transformation with the maximum number of transformations generated by the random experiments in its \( \delta \)-neighborhood and \( t^{\text{opt}} \) the transformation maximizing \( f(t) \). Let \( q \) denote the failure probability from Lemma 13 in terms of the number of votes \( M \) and the error tolerance \( \eta \).

Since \( |t^*(A) \cap B| \leq |t^{\text{opt}}(A) \cap B| \) holds by definition, we only have to show that \( |t^*(A) \cap B| \geq |t^{\text{opt}}(A) \cap B| - \varepsilon |A| \). By Lemma 16, \( h(t^*) \geq h(t^{\text{opt}}) - 2\eta/\mu \delta - 6L\delta \) with probability at least \( 1-q \).

For algorithm PROBMATCHRM3+1 the density function \( h(t) = f^2(t)/c \), where \( c \) is the constant from Lemma 3. The Lipschitz constant is \( L = 2(\sqrt{2} + 2\pi D)\Delta \min(|A|,|B|)/c \) by Lemma 11, where \( D \) is the diameter and \( \Delta \) the length of the boundary of \( A \), and the size of the \( \delta \)-neighborhood is \( \mu \delta = 8\delta^3 \). In the proof of Lemma 11 we actually showed a stronger bound on the Lipschitz constant (Equation (11)), namely \( L_{3+1} = 2(\sqrt{2} + 2\pi D)\Delta \sup_z f(z)/c \), which is \( 2(\sqrt{2} + 2\pi D)\Delta f(t^{\text{opt}})/c \). This stronger bound is used in the computations below.

Additionally, since the shapes \( A \) and \( B \) are \( \kappa \)-fat, and the shape \( A \) is the one with the smaller largest inscribed circle, the maximal area of overlap of \( A \) and \( B \) under rigid motions is at least as large as the area of the largest inscribed circle in \( A \), that is, \( f(t^{\text{opt}}) \geq \kappa |A| \).

By Lemma 10 we get that with probability at least \( 1-q \)

\[
\frac{1}{c} (f(t^{\text{opt}}) - f(t^*)) (f(t^{\text{opt}}) + f(t^*)) = \frac{f(t^{\text{opt}})^2}{c} - \frac{f(t^*)^2}{c} = h(t^{\text{opt}}) - h(t^*) \leq \frac{2\eta}{\mu \delta} - 6L\delta = \frac{2\eta}{8\delta^3} + 6\delta 2(\sqrt{2} + 2\pi D)\Delta f(t^{\text{opt}})
\]

Hence,

\[
f(t^{\text{opt}}) - f(t^*) \leq \frac{2\eta c}{8\delta^3 (f(t^{\text{opt}}) + f(t^*))} + \frac{6\delta 2(\sqrt{2} + 2\pi D)\Delta f(t^{\text{opt}})}{f(t^{\text{opt}}) + f(t^*)} \leq \frac{\eta c}{4\delta^3 f(t^{\text{opt}})} + \frac{12\delta (\sqrt{2} + 2\pi D)\Delta f(t^{\text{opt}})}{f(t^{\text{opt}})} \tag{since \( f(t^*) > 0 \)}
\]

\[
\leq \frac{\eta c}{4\delta^3 |A|} + 12\delta (\sqrt{2} + 2\pi D)\Delta \tag{since \( f(t^{\text{opt}}) \geq \kappa |A| \)}
\]

\[
\leq \frac{\eta |B| |A|}{4\delta^3 \kappa} + 12\delta (\sqrt{2} + 2\pi D)\Delta \tag{since \( c \leq |A|^2 |B| \) by La. 21}\}
\]

Restricting this error to be at most \( \varepsilon |A| \) and maximizing the expression for \( \eta \) we get that the optimal values for \( \delta \) and \( \eta \) are

\[
\delta = \frac{\varepsilon |A|}{16(\sqrt{2} + 2\pi D)\Delta} \quad \text{and} \quad \eta = \frac{\varepsilon^4 \kappa |A|^3}{16^3 |B|(\sqrt{2} + 2\pi D)^3 \Delta^3} \quad .
\]

The probability of failure is \( q = 2M^3 e^{-\eta^2(M-3)/8} \leq e^{-\eta^2(M-3)/16} \). Analogous to the proof of Theorem 1 we can show that \( q \leq \tau/2 \) for all \( M \geq \max\{16/\eta^2 \log(2/\tau), \ 112/\eta^2 \log(112/\eta^2)\} \).
Thus, if the number of recorded votes is

\[ M \geq k \cdot C' \frac{d}{\varepsilon^2 K^2} \log \left( \max \left\{ \frac{1}{\tau}, \frac{C'}{\varepsilon K} \right\} \right), \]

where \( C' = |B| \Delta^6 D^6/|A|^6 \), \( \Delta \) is the length of the boundary of \( A \), \( D \) is the diameter of \( A \), and \( k \) is an appropriate constant, then the area of overlap determined by the algorithm differs by at most \( \varepsilon |A| \) from the maximal area of overlap with probability at least \( 1 - \tau/2 \).

Next we determine the total number \( N \) of random samples that the algorithm needs to generate in order to record at least \( M \) votes with probability at least \( 1 - \tau/2 \). For that purpose we first determine the probability that one randomly generated sample is not rejected.

Let \( C_A \) and \( C_B \) denote the largest inscribed circles in \( A \) and \( B \), respectively. And let \( r_A, r_B \) denote the radii of \( C_A \) and \( C_B \). By the definition of \( \kappa \)-fatness \( |C_A| \geq \kappa |A| \) and \( |C_B| \leq \kappa |B| \), and by a precondition of the theorem \( r_A \leq r_B \).

Consider a circle \( C'_B \) of radius \( r_A/2 \) contained in \( A \) and a circle \( C'_B \) concentric with \( C_B \) of radius \( r_B - r_A/2 \geq r_B/2 \) in \( B \). The area of \( C'_B \) is at least \( \kappa |A|/4 \) and the area of \( C'_B \) is at least \( \kappa |B|/4 \). Then the probability that two randomly selected points \( a_1 \) and \( a_2 \) from \( A \) are both contained in \( C'_B \) is at least \( (\kappa/4)^2 \). The distance between \( a_1 \) and \( a_2 \) is at most \( r_A/2 \). The probability that a randomly selected point \( b_1 \) from \( B \) is contained in \( C'_B \) is at least \( \kappa/4 \), and by construction, the complete circle centered at \( b_1 \) with radius equal to the distance between \( a_1 \) and \( a_2 \) is completely contained in \( C_B \subset B \). Therefore, for every choice of two points in \( C'_A \) and a point in \( C'_B \) and for every randomly chosen direction the random sample induces a vote in transformation space. The probability that one random sample is not rejected is then at least as large as \( (\kappa/4)^2 \). In the following this probability is denoted by \( p \).

Our algorithm generates in every step random samples independently. For each sample the probability not to be rejected is at least \( p \). Then the expected number of valid samples after \( N \) steps is at least \( pN \). Let \( X \) denote the number of valid samples after \( N \) steps. Using the Chernoff bound (Theorem 11) we can determine the number of steps \( N \) for which \( X \) is not much smaller than \( pN \) with high probability:

\[ P \left( X < pN - \xi N \right) < 2e^{-\xi^2 N/2}, \]

for all \( 0 < \xi < 1 \). For \( \xi = p/2 \) we have \( P \left( X < \frac{p}{2}N \right) < 2e^{-p^2 N/8} \). Restricting this failure probability to be at most \( \tau/2 \) we get that for \( N \geq 8p^{-2} \ln(4/\tau) \) the number of votes \( X \) is at least \( pN/2 \) with probability at least \( 1 - \tau/2 \). Then with \( N \geq 2M/p \) random samples the algorithm generates at least \( M \) votes with probability at least \( 1 - \tau/2 \).

Finally, choosing

\[ N \geq \max \left\{ \frac{2M}{p}, \frac{8}{p^2} \ln(4/\tau) \right\} = \max \left\{ k_1 \cdot \frac{C'}{\varepsilon^2 K^5} \log \left( \max \left\{ \frac{1}{\tau}, \frac{C'}{\varepsilon K} \right\} \right), \frac{k_2 \cdot 1}{\varepsilon^5 K^5} \right\}, \]

with appropriate constants \( k_1, k_2 \), we get that with probability at least \( 1 - \tau/2 \) the number of recorded votes is sufficiently large, and therefore, with probability at least \( 1 - \tau/2 \) the approximation of the maximum area of overlap differs from the optimum by at most \( \varepsilon |A| \). \( \square \)

Proof of Theorem 4. For a given arrangement \( \mathcal{A} \) and an error tolerance \( \varepsilon \) the depth approximation algorithm of [3] finds a point \( t^{app} \) such that the depth of \( t^{app} \) is at least \( \varepsilon \) times the maximum depth in \( \mathcal{A} \). It remains to show that with high probability the area of overlap induced by \( t^{app} \) is a good approximation of the maximal area of overlap.

Let \( h(t) \) be the density of the probability distribution \( P \) in the transformation space induced by the algorithm, and \( L \) the Lipschitz constant of \( h \). Let \( \mathcal{A} \) be the arrangement of \( \delta \)-neighborhoods of the transformations resulting from the random experiments for some parameter \( \delta > 0 \) which will be specified later. Additionally we will use an error tolerance value \( \eta > 0 \) when applying lemmas or corollaries. The parameter \( \eta \) will also be computed later.
Let \( t^* \) be a transformation with maximum depth in the arrangement \( \mathcal{A} \), \( t^{\text{app}} \) the transformation approximating the maximum depth, i.e., \( X_N^\delta(t^{\text{app}}) \geq (1 - \eta)X_N^\delta(t^*) \), and \( t^{\text{opt}} \) the transformation maximizing \( f(t) \). And let \( q \) denote the failure probability from Lemma 13.

Applying Lemma 10 and Corollary 15 to \( t^{\text{app}} \) and error tolerance \( \eta \) we get

\[
|\mu_\delta h(t^{\text{app}}) - X_N^\delta(t^{\text{app}})/N| \leq |\mu_\delta h(t^{\text{app}}) - P(B^{\text{app}}_\delta)| + |P(B^{\text{app}}_\delta) - X_N^\delta(t^{\text{app}})/N| \\
\leq \eta + 5L\mu_\delta \delta
\]

and, likewise, by Lemmas 10 and 13

\[
|\mu_\delta h(t^{\text{opt}}) - X_N^\delta(t^{\text{opt}})/N| \leq L\mu_\delta \delta + \eta.
\]

Since \( |t^{\text{app}}(A) \cap B| \leq |t^{\text{opt}}(A) \cap B| \) holds by definition, we only have to show \( |t^{\text{app}}(A) \cap B| \geq |t^{\text{opt}}(A) \cap B| - \varepsilon|A| \).

Consider Case 1: \( X_N^\delta(t^{\text{app}}) \geq X_N^\delta(t^{\text{opt}}) \). Then

\[
h(t^{\text{app}}) \geq (X_N^\delta(t^{\text{app}}) - \eta - 5L\mu_\delta \delta)/\mu_\delta \quad \text{by (6)}
\]

\[
\geq (X_N^\delta(t^{\text{opt}}) - \eta - 5L\mu_\delta \delta)/\mu_\delta
\]

\[
\geq (\mu_\delta h(t^{\text{opt}}) - \eta - L\mu_\delta \delta - 5L\mu_\delta \delta)/\mu_\delta \quad \text{by (7)}
\]

\[
= h(t^{\text{opt}}) - 2\eta/\mu_\delta - 6L \delta.
\]

If \( X_N^\delta(t^{\text{app}}) < X_N^\delta(t^{\text{opt}}) \) (Case 2) we have that

\[
X_N^\delta(t^{\text{app}}) < X_N^\delta(t^{\text{opt}}) \leq X_N^\delta(t^*) \quad \text{and} \quad |X_N^\delta(t^{\text{app}}) - X_N^\delta(t^*)| \leq \eta X_N^\delta(t^*) .
\]

It follows that also \( |X_N^\delta(t^{\text{app}}) - X_N^\delta(t^{\text{opt}})| \leq \eta X_N^\delta(t^*) .\)

Now we can bound the difference \( |\mu_\delta h(t^{\text{app}}) - \mu_\delta h(t^{\text{opt}})| \):

\[
|\mu_\delta h(t^{\text{app}}) - \mu_\delta h(t^{\text{opt}})| \leq |\mu_\delta h(t^{\text{app}}) - P(B^{\text{app}}_\delta)| + |P(B^{\text{app}}_\delta) - X_N^\delta(t^{\text{app}})/N| \\
+ |X_N^\delta(t^{\text{app}})/N - X_N^\delta(t^{\text{opt}})/N| \\
+ |X_N^\delta(t^{\text{opt}})/N - P(B^{\text{opt}}_\delta)| + |P(B^{\text{opt}}_\delta) - \mu_\delta h(t^{\text{opt}})| .
\]

Applying Lemma 10 to the first term of the expression, Corollary 15 to the second, Lemma 13 to the fourth, Lemma 10 to the fifth, and bounding the third term by \( \eta X_N^\delta(t^*)/N \leq \eta \) from above we get:

\[
|\mu_\delta h(t^{\text{app}}) - \mu_\delta h(t^{\text{opt}})| \leq L\mu_\delta \delta + \eta + 4L\mu_\delta \delta + \eta + \eta + L\mu_\delta \delta
\]

\[
= 3\eta + 6L\mu_\delta \delta .
\]

Then in Case 1 and in Case 2 \( h(t^{\text{app}}) \geq h(t^{\text{opt}}) - 3\eta/\mu_\delta - 6L \delta \). Observe that this error bound for \( t^{\text{app}} \) differs from the bound for \( t^* \) in Lemma 10 only by a constant in the summand \( \eta/\mu_\delta \). Therefore we can complete the proof of the Theorem 4 by the same arguments as in the proof of Theorem 1 with values of \( \delta \) and \( \eta \) that differ from Equations (3), (4), and (5) only by constants.

5 Open Questions

We showed that our algorithm is a relative error approximation under the assumption that the maximal area of overlap of the two input shapes is at least a small constant fraction of one of the shapes. This is a reasonable assumption, but nevertheless it would be interesting to know whether the algorithm is a relative error approximation without further assumptions on the shapes.

Furthermore, it might be reasonable to use measure theoretic methods for the analysis of the algorithm. We can show that \( X_N^\delta(t)/N \) converges almost surely uniformly to \( P(B^\delta_\mu) \) on \( T \), using the Uniform Law of Large Numbers II, as stated in [S]. But it appears difficult to determine the
convergence rate to deduce bounds on the required number of random experiments by measure theoretic methods.

It is an interesting question how to apply our probabilistic technique to matching shapes under similarity maps. The straightforward technique of choosing a pair of random points from $A$ and one from $B$ and giving a vote to the corresponding similarity map does not lead to the desired result.

Furthermore, choosing three points in each shape defines a unique affine transformation that maps the points onto each other, so there is a canonical version of the algorithm for affine transformations. It would be interesting to know whether this algorithm computes something useful if the parametrization of the space and the definition of the neighborhoods are chosen cleverly.
