The features of net baryon productions and collective flow in relativistic heavy-ion collisions at energies reached at the CERN Large Hadron Collider (LHC), BNL Relativistic Heavy Ion Collider (RHIC), CERN Super Proton Synchrotron (SPS) and BNL Alternating Gradient Synchrotron (AGS) with the model of Non-Uniform Flow Model (NUFM) are systematically studied in this paper. Especially we predict the feature of net baryon productions and collective flow at LHC $\sqrt{s_{NN}}=5500$ GeV basing on the detailed study of that at RHIC $\sqrt{s_{NN}}=62.4$ and $200\text{GeV}$. The dependencies of the features of baryon stopping and collective flow on the collision energies and centralities are investigated.

Keywords: Non-Uniform Flow Model, LHC, Collective flow, net proton distributions

I. INTRODUCTION

Over the last two decades, relativistic heavy ion collisions$^{[1,2]}$ have been studied experimentally at increasingly higher center-of-mass energies at the Brookhaven Alternating Gradient Synchrotron AGS ($\sqrt{s_{NN}} < 5$ GeV), the CERN Super Proton Synchrotron SPS ($\sqrt{s_{NN}} \leq 20$ GeV) and the Brookhaven Relativistic Heavy Ion Collider RHIC ($\sqrt{s_{NN}} \leq 200$ GeV). As discussed in this article, the data collected in these experiments display remarkable generic trends as a function of system size and kinematic variables. The Large Hadron Collider LHC at CERN will study heavy ion collisions at a center-of-mass energy $\sqrt{s_{NN}} = 5.5\text{ TeV}$, which is a factor 27 higher than the maximal collision energy at RHIC. This is an even larger increase in center of mass energy than the factor 10 in going from the CERN SPS to BNL RHIC. It leads a significant extension of the kinematic range in longitudinal rapidity and transverse momentum. The collectivity of high energy density matter is one of the important properties to understand high-energy heavy-ion collisions$^{[3,4]}$. It is also challenging to understand how collectivity is generated during collisions.

There has been a lot of work in recent years on thermal and collective flow model calculations$^{[6,18]}$ of heavy ion collisions to RHIC data and extrapolating them to the higher LHC energies. Here we should mention some kinds of models of thermal and collective flow. The first one is the spherically-expanding source model that may be expected to approximate the fireball of an isotropic thermal distribution created in lower-energy collisions.

As the collision energy increases, stronger longitudinal flow is formed which leads to a cylindrical geometry according to the second kind model$^{[10,17]}$. It accounted for the anisotropy of longitudinal and transverse direction by adding the contribution from a set of fireballs with centers located uniformly in the rapidity region in the longitudinal direction. It can account for the wider rapidity distribution at AGS and SPS when comparing to the prediction of pure thermal isotropic model.

Bjorken$^{[13]}$ postulated that the rapidity distribution of produced particles establishes a plateau at mid-rapidity which has been formulated for asymptotically high energies. It is well known that collisions at available heavy-ion energy regions of AGS, SPS and RHIC are neither fully stopped nor fully transparent$^{[19–27]}$, although a significant degree of transparency is observed. But the central plateau structure becomes more and more obvious as the collision energy increases to SPS and RHIC.

As the collision energy increases to LHC, which is a factor 27 higher than the maximal collision energy at RHIC, the kinematic range in the longitudinal direction will increase considerably and the net-baryon density will decrease quickly at mid-rapidity. It seems reasonable to realize that the plateau proposed by Bjorken$^{[18]}$ at mid-rapidity at LHC energy region has been established. For the net baryon distributions, Ref.$^{[28]}$ realized the collision of high-energy heavy ions can be divided into the two different energy regions: the baryon-free quark gluon plasma (QGP) region (or the pure QGP region) with $\sqrt{s} > 100\text{GeV}$ per nucleon, and the baryon-rich QGP region (or the "stopping" region) with $\sqrt{s} \sim 5 – 10\text{GeV}$ per nucleon, which corresponds to about many tens of GeV per projectile nucleon in the laboratory system. In the baryon-free QGP region, we need to know the nuclear stopping power to determine whether the beam baryons and the target baryons will recede away from the center of mass without being completely stopped, leaving behind QGP with very little baryon content.

The NUFM (Non-Uniform Flow Model)$^{[29,34]}$ realized that the fireballs keep some memory on the motion of the incident nuclei, and therefore the distribution of fireballs, instead of being uniform in the longitudinal direction, is
more concentrated in the motion direction of the incident nuclei, i.e. more dense at large absolute value of rapidity. It will not only lead to anisotropy in longitudinal-transverse directions, but also render the fireballs (especially for those baryons) distributing non-uniformly in the longitudinal direction. NUFM may analyze the central dip of baryon rapidity distribution by assuming that the centers of fireballs are distributed non-uniformly in the longitudinal phase space.

This paper is organized as follows. In Sec. 2 we give a brief review the Non-Uniform Flow Model in the longitudinal direction. The comparison and analysis of baryon distribution of AGS, SPS, RHIC and LHC with the results of the model given in Sec. 3. Section 4 gives a summary and conclusions.

II. NON-UNIFORM FLOW MODEL NUFM

The NUFM model we considered contains three distinct assumptions:

1. It is argued that the transparency/stopping of relativistic heavy-ion collisions should be taken into account more carefully. A more reasonable assumption is that the fireballs keep some memory on the motion of the incident nuclei, and therefore the distribution of fireballs, instead of being uniform in the longitudinal direction, is more concentrated in the direction of motion of the incident nuclei, i.e. more dense at large absolute value of rapidity. It will not only lead to anisotropy in longitudinal-transverse directions, but also render the fireballs (especially for those baryons) distributing non-uniformly in the longitudinal direction.

2. The freeze-out temperatures are assumed to be about the same around 120 MeV whether it is at higher LHC or at lower AGS energy region. Since the temperature at freeze-out exceeds 100 MeV, the Boltzmann approximation seems reasonable to study LHC at freeze-out.

3. In order to express the non-uniformity of flow in the longitudinal direction, an ellipticity parameter $e$ is introduced through a geometrical parametrization. For the central collisions, the nuclear stopping can be studied by the range of rapidity of emission source in the center-of-mass system.

We have previously used NUFM to study the net proton rapidity among AGS, SPS and RHIC energy regions. But for the RHIC energy regions, we made an earlier error to predict the distributions of net proton distributions since we neglected the effects of the baryon number conservation. Therefore, it is necessary to reanalyze the features of net proton rapidity distributions among AGS to RHIC by taking into account the baryon number conservation. It is found that when we consider the baryon number conservation, the features of the distributions at RHIC are completely different from the results given before, especially at large absolute rapidity region. On the other hands, with the run of forthcoming LHC, the predictions of the features of net proton rapidity distributions at LHC are also important. We will restudy the features of net proton rapidity distributions among AGS to RHIC by using NUFM, and make prediction for the features of forthcoming LHC in this paper. In the following, we will firstly make a simple introduction to the NUFM.

A parametrization for such a non-uniform distribution can be obtained by using an ellipse-like picture on emission angle distribution. In this scenario, the emission angle is:

$$\theta = \tan^{-1}(e \tan \Theta).$$

Here, the induced parameter $e(0 \leq e \leq 1)$ represents the ellipticity of the introduced ellipse which describes the non-uniform of fireball distribution in the longitudinal direction. The detailed discussions of the NUFM were given by ref. The rapidity distribution of NUFM is:

$$\frac{d\nu_{\text{NUFM}}}{dy} = eK m^2 T \int_{-y_{e0}}^{y_{e0}} \rho(y_e) dy_e (1 + 2\Gamma + 2\Gamma^2)e^{-1/\Gamma},$$

where $y_{e0}$ and $e$ are the important parameters in this paper, $y_{e0}$ is the rapidity limit which confines the rapidity interval of longitudinal flow and $e$ can describe the non-uniform in the longitudinal direction of the collective flow. In eq. (2),

$$\Gamma = T/m \cosh(y - y_e),$$

$m$ is the mass of produced particle, $T$ is the temperature parameter, and $y_e$ is the rapidity of collective flow, and

$$\rho(y_e) = \int \frac{1 + \sinh^2(y_e)}{1 + e^2 \sinh^2(y_e)}$$

is the flow distribution function in the longitudinal direction, and $e$ is a parameter which represents the ellipticity of the introduced ellipse describing the non-uniform of fireball distribution in the longitudinal direction. It may be figured out from Eq.2 to Eq.4 that the larger the parameter $e$, the flatter the distribution function $\rho(y_e)$, the more uniform the longitudinal flow distribution. When $e \Rightarrow 1$, the longitudinal flow distribution is completely uniform $\rho(y_e) \Rightarrow 1$ and returns to uniform flow. The other important parameter $y_{e0}$ describes the kinematic region and can determine the width of the distribution.

In order to discuss the dependence of velocity of collective flow on collision energy in the central mass(CM) system, we give a calculation of the average velocity in the longitudinal direction as $<\beta_L> = \tanh(y_{e0}/2)$ and $<\beta_\gamma> = \tanh(y_{e0}/2)$, where $\gamma = 1/\sqrt{1 - <\beta_L>^2}$ is the Lorentz factor. Therefore $y_{e0}$ can also determine the average velocity of collective flow in the longitudinal direction.
### III. THE NET PROTON DISTRIBUTIONS AT THE WHOLE AGS TO LHC ENERGY REGIONS

We use the form of the NUFM model as described in Section II and fit the experimental data with the parameters $y_{e0}$ and $e$ that have been assumed to be different for different energies, as given in Table I. The systematics of these parameters provide useful information on the collective flow of baryons in these reactions.

Comparing with NUFM calculation before [30], we consider the influence of baryon number conservation at this time when discussing the distributions. Fig.1(a) shows net-proton rapidity distributions measured at AGS, and SPS energies. Fig.1(b) shows net-proton rapidity distributions of the top 5% central collisions measured at RHIC $\sqrt{s_{NN}} = 62.4$ GeV and $\sqrt{s_{NN}} = 200$ GeV, respectively. The solid lines are our NUFM calculation results from AGS to RHIC and the dotted line is the calculation result for that of LHC. It can be seen from the Fig.1 that NUFM model can fit the experimental results from AGS to RHIC, and reproduce central dip of the rapidity distribution of the proton at SPS and RHIC in agreement with the experimental findings. $y_{e0}$ is approximately equal to the half width of fit distribution. In the sense, the parameter $y_{e0}$ represent the kinetic region of collective flow in the longitudinal direction. The parameter of $T$ is chosen to be 0.12 GeV.

The features of non-uniform flow distributions show strong energy dependence from AGS to RHIC. For example: at AGS ($e = 0.82$, $E_{lab} = 10.8$ GeV), the net proton distribution has a peak at mid-rapidity, and the distribution is narrower that of the other two energies. The collective flow is approximately uniform. While at SPS ($e = 0.61$) a dip begins to show in the middle of rapidity distribution. While at RHIC $\sqrt{s_{NN}} = 62.4$ GeV and $\sqrt{s_{NN}} = 200$ GeV the distributions show deep dip and the non-uniform parameter $e$ take 0.34 and 0.31, respectively. According to our calculation as the collision energy increases, the net baryon distributions become wide for the whole rapidity distribution and the net baryon densities become small at the middle rapidity ($y \approx 0$) region.

We also speculate the feature of non-uniform flow distributions at LHC in Fig.1(b). As mentioned before, although collisions at available heavy-ion energy regions of AGS, SPS and RHIC are neither fully stopped nor fully transparent, but the plateau structure becomes more and more obvious as the collision energy increases to SPS and RHIC. It leads a significant extension of the kinematic range ($y_{e0}$) in longitudinal rapidity and the net-baryon distribution at the central rapidity region decreases at LHC. It seems reasonable that we conjecture the kinematic range ($y_{e0}$) at LHC $\sqrt{s_{NN}} = 5500$ GeV approaches to the incident beam rapidity $y_p$, which is about 1.5 times of that at RHIC $\sqrt{s_{NN}} = 200$ GeV ($y_{e0} = 5.32$).

By making a analysis of the dependence of $dN/dy\big|_{y=0}$ on incident beam rapidity $y_p$ from SPS ($\sqrt{s_{NN}} = 17.2$ GeV) to RHIC ($\sqrt{s_{NN}} = 62.4$ and 200 GeV) experiments, in which the rapidity distribution obviously show central dip feature, we can provide a relationship between $dN/dy\big|_{y=0}$ and incident beam rapidity $y_p$

$$dN/dy\big|_{y=0} = 51.0 - 22.0 \cdot \log(y_p) \quad (5)$$

shown in Fig.2. According to the speculation, the magnitude of rapidity density at central rapidity $y \approx 0$ at LHC is about 3.63 which is about 1/4 times of that at RHIC 200GeV. We can get $e = 0.19$ to fit the LHC distribution by using the NUFM and the baryon number conservation law.

At LHC, a broad dip in the middle of rapidity region has developed spanning several units of rapidity, indicating that collisions are quite transparent at LHC energy region. According to our study, $e = 0.19$ at LHC gives a more obvious non-uniform feature than that of AGS, SPS and RHIC energy region, and the detailed results are shown in Table I.

From Fig.3, we know that as the incident energy increases, the longitudinal flow distribution becomes more non-uniform. $e = 0.19$ at LHC $\sqrt{s_{NN}} = 5500$ GeV is smaller than $e = 0.31$ at RHIC $\sqrt{s_{NN}} = 200$ GeV, and $e = 0.82$ at AGS ($E_{lab} = 10.8$ GeV). The central rapidity density at AGS is the largest in the whole AGS, SPS, RHIC and LHC energy regions in Fig.3.

Figure 4 shows proton rapidity distribution at different collision energies at AGS and SPS, and the solid lines are the calculation results. From Fig.4 we know that proton distribution shows uniform distribution feature in the longitudinal direction at the AGS(2 GeV-8 GeV) according to NUFM. But for Pb + Pb interactions (158 GeV) at SPS,
FIG. 2: The dependence of central rapidity density $dN/dy|_{y=0}$ on incident beam rapidity $y_p$ from SPS ($\sqrt{s_{NN}}=17.2\,\text{GeV}$) to RHIC ($\sqrt{s_{NN}}=62.4$ and 200 GeV) experiments. The solid circles are from experimental results, the solid triangle is the speculating. The real line is the fit curve of Eq.5.

$e = 0.61$ shows non-uniform distribution feature in the longitudinal direction.

From Fig.6(a) and Table.1, we know that from AGS to SPS, average rapidity loss $<\delta y>$ increases linearly with $y_p$. When discussing at RHIC, we study the average rapidity loss at $\sqrt{s_{NN}} = 62.4$ and 200 GeV, a new linear
FIG. 4: Proton rapidity distributions for Au + Au interaction at AGS. The experimental data is from Ref. [22–27] and the solid lines are the calculation results. The whole fitted parameters $e$ and quanta $y_{e0}$ are given by Table 1.

FIG. 5: Proton rapidity distributions for Au + Au (10.8 GeV) and Si + Al (14.6 GeV) interactions at AGS, and for Pb + Pb (158 GeV) and S + S (200 GeV) interactions at SPS. The experimental data is from Ref. [22–27], and the solid lines are the calculation results. The whole fitted parameters $e$ and quanta $y_{e0}$ are given by Table 1.

Increasing relationship is established from SPS to RHIC, but begins to increase slowly and deviates from that of from AGS to SPS. We also predict the nuclear stopping power at LHC. The dependence of $<\beta\gamma>_L$ on incident proton rapidity in the whole AGS, SPS, RHIC and LHC energy regions are shown in Fig. 6(b). We can find a kind of Log increasing dependence of $<\beta\gamma>_L$ on incident proton rapidity.

FIG. 6: The dependence of average rapidity loss $<\delta y>$ (a) and $<\beta\gamma>_L$ (b) on incident proton rapidity in the whole AGS, SPS, RHIC and LHC energy regions. The dependence of $<\beta\gamma>_L$ on incident proton rapidity.

As shown in Figure 7, NUFM can fit the net baryon distribution at different centralities of 0%-10%, 10%-20%, 20%-40%, and 40%-60% at RHIC $\sqrt{s_{NN}} = 200$ GeV. From Figure 8 and Table 2, we know that as the centrality increases, the kinematic region and average velocity $<\beta\gamma>_L$ in the longitudinal direction increases and

FIG. 7: Rapidity distribution of net baryons in Au + Au collisions at RHIC energy of $\sqrt{s_{NN}} = 200$ GeV are compared with preliminary BRAHMS net baryon data for different centralities of 0%-10%, 10%-20%, 20%-40%, and 40%-60%.

FIG. 8: Rapidity distribution of net baryons in Au + Au collisions at RHIC energy of $\sqrt{s_{NN}} = 200$ GeV for different centralities of 0%-10%, 10%-20%, 20%-40%, and 40%-60%.
the distribution becomes wide. On the other hands, the stopping power diminishes as the centrality increases. It is surprise to find that the non-uniformity $e$ keeps unchanged.

**FIG. 8:** The dependence of average rapidity loss $<\delta y>$ (Fig.8a), $<\beta y>_L$ (Fig.8.b) and kinematic region $y_{00}$ (Fig.8.c) on the collision centrality at RHIC $\sqrt{s_{NN}} = 200$ GeV.

### IV. SUMMARY AND CONCLUSION

Net proton rapidity distributions have been measured by several experiments at different energies from AGS to RHIC. The compiled data are shown in Fig. 1. The net proton rapidity distributions are reconstructed among the AGS, SPS, RHIC and LHC energy regions by using NUFM in this work. We can predict the distribution feature in the fragmentation region of the net proton distributions at RHIC although RHIC [19] only provided the multiplicity distribution of net protons at the central rapidity region. While at RHIC $\sqrt{s_{NN}} = 62.4$GeV and $\sqrt{s_{NN}} = 200$GeV the distributions show deep dip and the non-uniform parameter $e$ take 0.34 and 0.31, respectively. According to our calculation as the collision energy increases, the net baryon distributions become wide for the whole rapidity distribution and the net baryon densities become small at the middle rapidity ($y \approx 0$) region.

The features of non-uniform flow distributions show strong energy dependence from AGS to RHIC. For example: the net proton distribution at AGS has a peak at mid-rapidity, and the distribution is narrower than that of the other two energies. The collective flow is approximately uniform. While at SPS a dip begins to show in the middle of rapidity distribution. The distributions at RHIC $\sqrt{s_{NN}} = 62.4$GeV and $\sqrt{s_{NN}} = 200$GeV show the non-uniform feature of deep dip. It is found that the distributions become wider and wider for the whole rapidity distribution and the densities of net baryon in the middle of rapidity region ($y \approx 0$) become smaller and smaller.

Here, we should mention that quite a few theoretical models [36–40] can give equally good representation of the data of particle productions in relativistic heavy ion collisions. These models give some different physical pictures for the research. In Ref. [38] in order to determine whether a pure quark-gluon plasma with no net baryon density could be formed in the central rapidity region in relativistic heavy ion collisions, Wong [38] estimated the baryon distribution by using a Glauber-type multiple collisions in which the nucleons of one nucleus degrade in energy as they make collisions with nucleons in the other nucleus. It was found that in the head-on collision of two heavy nuclei($A \geq 100$), the baryon rapidity rapidity distributions have broad peaks and extend well.

The plateau structure becomes more and more obvious as the collision energy increases to RHIC although collisions at available heavy-ion energy regions of AGS, SPS and RHIC are neither fully stopped nor fully transparent. It leads a significant extension of the kinematic range ($y_{00}$) in longitudinal rapidity and the net-baryon distribution at the central rapidity region decreases at LHC. We can study the feature of net baryon distributions at LHC by using the NUFM and the baryon number conservation law.

Detailed energy dependence of the net baryon distribution among AGS, SPS and RHIC shows a clear transition from the baryon stopping region to the baryon transparent region. It is found that from AGS to SPS, average rapidity loss $<\delta y>$ increases linearly with $y_{p}$, but begins to increase slowly and deviates from the linear relationship when at RHIC and LHC. It may suggests the difference of the interaction mechanism in RHIC and LHC from AGS and SPS. The detailed study of net proton rapidity distributions from AGS to LHC will deepen our study of the relativistic heavy-ion collisions.

It is found that the transparency of relativistic heavy-ion collisions increases as collision energy increases, i.e. the higher the collision energy, the more transparent of the collision system by analyzing the proton rapidity distribution. The phase space of heavy collision system is nearly completely uniform in the longitudinal direc-
tion at AGS. The phase space of proton distributes non-uniformly in the longitudinal direction at SPS and RHIC. At LHC, a broad dip in the middle of rapidity region has developed spanning several units of rapidity, indicating that collisions are quite transparent at LHC energy region. According to our study, \( e = 0.19 \) at LHC gives a more obvious non-uniform feature than that of AGS, SPS and RHIC energy region. By reanalyzing RHIC, we obtain a wider rapidity distribution than that of Ref [30].
