Abstract

We introduce two new criteria based on the work of Duchon and Robert (2000 Nonlinearity \textbf{13} 249) and Eyink (2006 \textit{Phys. Rev. E} \textbf{74} 066302), which allow for the local detection of Navier–Stokes singularities in experimental flows. We discuss the difference between non-dissipative or dissipative Euler quasi-singularities and genuine Navier–Stokes dissipative singularities, and classify them with respect to their Hölder exponent $h$. We show that our criteria allow us to detect areas in a flow where the velocity field is no more regular than Hölder continuous with some Hölder exponent $h \leq 1/2$. We illustrate our discussion using classical tomographic particle image velocimetry (TPIV) measurements obtained inside a high Reynolds number flow generated in the boundary layer of a wind tunnel. Our study shows that, in order to detect singularities or quasi-singularities, one does not need to have access to the whole velocity field inside a volume, but can instead look for them from stereoscopic PIV data on a plane. We also provide a discussion about the link between areas detected by our criteria and areas corresponding to large vorticity. We argue that this link might provide either a clue about the genesis of these quasi-singularities or a way to discriminate dissipative Euler quasi-singularities and genuine Navier–Stokes singularities.

1. Introduction

Viscous incompressible flows are described by the incompressible Navier–Stokes equations (INSEs) in spacetime

\[ \partial_t u_i + u_j \partial_j u_i = -\frac{1}{\rho} \partial_i p + \nu \partial_j \partial_j u_i + f_i, \]  

(1)

\[ \partial_j u_j = 0, \]  

(2)

where Einstein summation convention over repeated indices is used. \( u_i(x,y,z,t) \) is the velocity field, \( p(x,y,z,t) \) the pressure field, \( \rho(x,y,z,t) \) the mass density, \( f_i(x,y,z,t) \) some forcing and \( \nu \) the molecular viscosity. A natural control parameter for the INSEs is the Reynolds number \( \text{Re} = \frac{LU}{\nu} \), which measures the relative importance of nonlinear effects compared to the viscous ones, and is built using a characteristic length \( L \) and velocity \( U \). The INSEs are the cornerstone of many physical or engineering sciences, such as astrophysics, geophysics and aeronautics, and are routinely used in numerical simulations.

However, from a mathematical point of view, it is not known whether the mechanism that tends to smooth out possible irregularities in the velocity field, i.e. viscous forces, is efficient enough to constrain \( u_i \) to remain smooth at all times. In two dimensions, the existence, unicity and smoothness theorems have been known for a long time [1–4]. In three dimensions however, it is still unclear whether the INSEs are a well-posed problem, i.e. whether their solutions remain regular or develop finite time, small-scale singularities. This motivated their inclusion in the AMS Millennium Clay Prize list [5]. Historically, the search for singularities in the INSEs was initiated by Leray [6–8] who introduced the notion of weak solutions (i.e. in the sense of distribution). This notion has since remained a framework of choice for those wishing to study their regularity. However, only partial regularity theorems have been obtained up to now. For instance, we know that, contrary to Euler equations, regularity of the solutions to the INSEs is ensured if the velocity field remains bounded [9–11]. Therefore, the problem of Navier–Stokes regularity is a velocity blow-up problem and may experimentally result in a breakdown of the incompressibility condition (2) [12–14]. Another well-known result about these potential singularities is that they are very rare events: according to the Caffarelli–Kohn–Nirenberg theorem, the singular set has a zero one-dimensional Hausdorff measure in spacetime [15]. This means that if they exist, singularities manifest themselves by a velocity which becomes arbitrarily large at one point in space, reaches infinity and immediately after becomes finite again.

In 1949, Onsager published his only paper in the field of turbulence [16, 17]. In this work, he realized that far from simply being a mathematical curiosity, the possible loss of smoothness in the velocity field could have important practical consequences. More precisely, he argued that if, at point \( x \), the velocity field cannot satisfy any regularity condition stronger than a Hölder condition

\[ |u(x + r) - u(x)| < Cr^h, \]  

(3)
with \( h \leq 1/3 \), then energy conservation is not ensured in the limit \( \nu \to 0 \) because there might exist an additional energy dissipation due to this lack of smoothness, which has nothing to do with viscosity. Let us note that Hölder continuity (3) is a weaker regularity condition than differentiability. Therefore, at first sight, it seems that Onsager’s assertion concerns the blow-up of the gradient of \( \mathbf{u} \). However, since Navier–Stokes singularities are velocity blow-ups, Onsager’s statement truly is about the blow-up of \( \mathbf{u} \) itself.

Onsager’s arguments are important for turbulence because they provide an alternative mechanism to Taylor’s [18, 19] in order to explain the fact that turbulent flows dissipate energy at a rate which is independent of \( \text{Re} \), for sufficiently large \( \text{Re} \). In the following years, Onsager’s conjecture attracted a lot of attention from mathematicians who tried to prove that \( h > 1/3 \) indeed implies that energy dissipation is zero when viscosity vanishes. In 2000, Duchon and Robert derived the corresponding local energy balance in Leray’s weak formalism, and were in addition able to express Onsager’s dissipation in terms of velocity increments [20]. Later, Eyink used the same formalism to prove that singularities may also produce a non-zero rate of velocity circulation decay, providing another interesting signature of singularities in terms of the cascade of circulation [21–23].

These physical consequences illustrate the interest of detecting potential singularities of the INSEs in order to advance our understanding of turbulence. This task is, however, complicated by the scarcity of the putative singularities. For example, the numerical detection of singularities requires the solving of the full INSEs at large Reynolds numbers, for a time long enough so that singularities might develop. These two constraints actually severely limit the quest for singularities and explain why there still is no final answer about their numerical detection. Part of the numerical limitations are relaxed when performing experiments with turbulent flows. Indeed, in a well-designed experiment, one can reach fairly easily large Reynolds numbers and monitor the results for a time long enough (minutes to hours) to accumulate enough statistics for reliable data analysis. In the past, the experimental detection of singularities of INSEs has been limited by the instrumentation, since only global (torque), or localized in space (Pitot, hot wire) or in time (slow imaging) velocimetry measurements were available. With the advent of modern particle image velocimetry (PIV), measurements of the velocity field at several points at the same time over the decimetric to sub-millimetric size range is now available, at frequencies from 1 Hz to 1 kHz, reviving the interest in the experimental detection of singularities of INSEs. The main challenge remains to find an appropriate detection method.

Clearly, the naive method consisting in tracking the velocity field and locating areas where the velocity becomes very large is unlikely to prove successful: it would require time and space resolved measurements, localized at the place where the singularity appears. With the present technology, this means zooming over a small area of the flow (typically a few mm²) and wait until a singularity appears. Since singularities are potentially very scarce, there is little chance that one will be able to detect such events. Moreover, if the velocity is indeed very high at this location, any neutral particle in the area will move very fast and leave the observation window in an arbitrarily small time. This is a problem for PIV or particle tracking velocimetry (PTV) measurements, which are based on particle tracking. An interesting alternative is provided by multifractal analysis, which is a classical but powerful method to detect singularities based on statistical multiscale analysis. Classical reviews on the method are provided in [24, 25]. With velocity fields as the input, the so-called multifractal spectrum can be obtained, quantifying the probability of the observation of a singularity of scaling exponent \( h \) through the fractal dimension \( D(h) \) of its supporting set. This method has been applied to experimental measurements of one velocity component at a single point at high Reynolds numbers in [24], where it was shown that the data are compatible with the multifractal picture, with a most
probable $h$ close to 1/3. Later Kestener and Arneodo [25] extended the method to 3D signals (3 components of the velocity field), and showed on a numerical simulation that the picture provided by the 1D measurements was still valid, with the most probable $h$ shifting closer to 1/3. To our knowledge, this method has never been applied to 3D experimental data. However, due to the statistical nature of the analysis, it appears difficult to obtain information regarding the possible instantaneous spatial distribution of singularities.

In the present paper, we suggest a new method for detecting singularities in experimental turbulent incompressible flows. This method is inspired by Onsager’s conjecture and based directly on the energy balance derived by Duchon–Robert (DR) [20] (section 2.1). The idea is to track singularities through scales by detecting the energy transfers that they produce. We will use DR’s results [20] as a criterion (hereafter referred to as DR criterion) which will tell us where to look (section 3). This criterion is easily implementable from now classical velocity measurements such as tomographic PIV (TPIV) or stereoscopic PIV (SPIV). Furthermore, we show that our approach provides a natural connection with the traditional cascade picture of turbulence, facilitating the interpretation of the detected singularities. We further discuss how the DR criterion compares with areas of intense vorticity (section 3.4). Finally, a result obtained by Eyink [21–23], and which resembles Duchon and Robert’s, will be investigated. This result concerns Kelvin’s theorem (section 4), and will give us indications on singularities with $h \leq 1/2$. Our discussion is illustrated using TPIV data obtained inside the turbulent boundary layer of a flow generated in a wind tunnel [26].

2. Mathematical tools

Lars Onsager was the first to make the connection between the regularity properties of the velocity field and kinetic energy conservation in Euler equations [16, 17, 23]. He conjectured that weak solutions of the Euler equations which are Hölder continuous with an exponent $h > 1/3$ conserve kinetic energy while those with $h \leq 1/3$ might not. Since then, efforts were made in order to prove this assertion [27, 28]. A milestone was reached with the work of Duchon and Robert [20], who derived the exact local form of the energy dissipation created by a loss of regularity in the velocity field, along with the corresponding energy balance. In this section, we provide the basic mathematical tools in order to understand these ideas.

2.1. Background on Onsager’s conjecture

A physical way of discussing Onsager’s conjecture is to consider a local space averaged (low-pass filtered) velocity field [29]. In the INSE, the unknown velocity and pressure fields contain information about the flow at all possible scales. Let us define a coarse-grained velocity field by taking the convolution of $u$ with some kernel $G_{\ell}$

$$u^\ell (x, t) = \int dr \, G_{\ell} (r) \, u(x + r, t),$$

where $G$ is a smooth filtering function with compact support on $\mathbb{R}^3$, even, non-negative, spatially localized and such that $\int dr \, G (r) = 1$. The function $G_{\ell}$ is rescaled with $\ell$ as $G_{\ell} (r) = \ell^{-3} G(r/\ell)$. This process of coarse-graining thus averages out fine details of the fields while keeping information about large scales. Formally, the coarse-grained velocity can be seen as a continuous wavelet transform of the velocity $u$ with respect to the wavelet $G$. Note, however, that since we have chosen $G$ to be of unit integral, it is not admissible, meaning
that the wavelet transform is not invertible. Let us now derive the equations satisfied by \( u^\ell_i \). Starting from the INSEs and applying the coarse-graining procedure we get

\[
\partial_t u^\ell_i + u^\ell_i \partial_j u^\ell_j = f^\ell_i - \partial_j p^\ell_j + \nu \partial_{jj} u^\ell_i,
\]

(5)

\[
\partial_j u^\ell_j = 0,
\]

(6)

where \( f^\ell_i = -\partial_j \tau^\ell_{ij} \) is called the turbulent force, and \( \tau^\ell_{ij} = (u_i u_j)^\ell - u^\ell_i u^\ell_j \) is the subscale stress tensor. We thus obtain a sequence of equations describing the dynamics at large scales. From these equations, together with the INSEs (1) and (2), we can derive a local energy balance at scale \( \ell \)

\[
\partial_t E^\ell + \partial_j J^\ell_j = -\Pi^\ell_{DR} - \mathcal{D}^\ell, \quad \text{(7)}
\]

where each term in equation (7) take the form

\[
E^\ell = \frac{u_i u_i}{2},
\]

(8)

\[
J^\ell_j = u_j E^\ell + \frac{1}{2} (p u_j + p^\ell u_j) + \frac{1}{4} \left[ (u_i u_i)^\ell - (u_i u_i) \right] - \nu \partial_j E^\ell + \nu \int dr \nabla_j G_\ell (r) u_i (x) u_i (x + r),
\]

(9)

\[
\Pi^\ell_{DR} = \frac{1}{4} \int dr \nabla_j G_\ell (r) \cdot \delta u_i (x, r) |\delta u (x, r)|^2,
\]

(10)

\[
\mathcal{D}^\ell = -\nu \int dr \nabla_j G_\ell (r) u_i (x) u_i (x + r),
\]

(11)

where \( \nabla \) is the derivative with respect to \( r \) and \( \delta u(x, r) = u (x + r) - u (x) \) [20, 29]. In equation (7), \( E^\ell \) represents the large-scale kinetic energy, \( J^\ell_j \) is the large-scale energy current in space, \( \Pi^\ell_{DR} \) describes the local amount of energy scattered through scale \( \ell \) (see [30] for an application to experimental measurements), and \( \mathcal{D}^\ell \) is the viscous energy dissipation at scale \( \ell \).

Taking the limit of infinitely small scales \( \ell \to 0 \), we obtain the local energy balance

\[
\partial_t E + \partial_j J_j = -\mathcal{D}_I - \mathcal{D}_v,
\]

(12)

where all the derivatives should be understood in the weak sense, i.e. in the sense of distributions. Moreover, the various terms of equation (12) take the form

\[
E = \frac{u_i u_i}{2},
\]

(13)

\[
J_j = u_j (E + p) - \nu \partial_j E,
\]

(14)

\[
\mathcal{D}_I = \lim_{\ell \to 0} \frac{1}{4} \int dr \nabla_j G_\ell (r) \cdot \delta u_i (x, r) |\delta u (x, r)|^2,
\]

(15)

\[
\mathcal{D}_v = \nu \partial_j u_i \partial_j u_i,
\]

(16)

and \( \mathcal{D}_I \) is called the local inertial energy dissipation. In the classical picture of turbulence, \( u \) remains smooth \( (u \in C^\infty) \) for all scales so that \( \delta u \sim \ell \) as \( \ell \to 0 \). In this case, \( \mathcal{D}_I = 0 \) and equation (12) is the usual local balance of energy. However, mathematically, it is not known...
whether an initially smooth solution of the INSEs remain smooth at all later times, and
Onsager’s key idea was to consider weaker regularity conditions on $u$. In particular, let us
consider a Hölder continuous velocity field with some exponent $h < 1$ (i.e. not necessarily
differentiable) at small scales. We have

$$|u(x + r) - u(x)| < Cr^h,$$

or equivalently

$$|\delta u(x, r)| = O(\ell^h).$$

(17)

(18)

Let us now define $\delta u(x, \ell) \overset{\text{def}}{=} \sup_{r < \ell} |\delta u(x, r)|$ [23]. We directly get that

$$\Pi_{DR}^{\ell} = O_{\ell \to 0} \left( \frac{\delta u(x, \ell)^3}{\ell} \right).$$

(19)

Therefore, if $u$ is Hölder continuous in space with exponent $h$, i.e. $\delta u(\ell) \sim \ell^h$, then

$$\Pi_{DR}^{\ell} = O_{\ell \to 0} (\ell^{3h-1}).$$

(20)

As a consequence, we see that if $h > 1/3$, $\Pi_{DR}^{\ell}$ vanishes as $\ell \to 0$ and Euler equations are
seen to conserve energy. On the other hand, it may well be that this condition does not hold, in
which case turbulent flows might keep on dissipating energy even if $\nu = 0$.

All the steps we have described here have been formalized for the first time in a rigorous
mathematical framework by Duchon and Robert [20]. They found the expression given in
equation (14) for the inertial dissipation, and showed that it does not depend on the choice
of the test function $G$. The key point of their work is that $DI$ appears in equation (12) as the
fraction of energy dissipated due to a lack of smoothness in the velocity field and has nothing
to do with viscosity.

2.2. Connection with traditional turbulence notions

2.2.1. The zeroth law of turbulence. It is a well-known experimental fact that for high enough
Reynolds numbers, the global dimensionless energy dissipation rate per unit mass $\epsilon$ is a non-
zero constant independent of Re. This observation was first reported by Taylor, in a paper
discussing turbulent pipe flows [31], and is known as the zeroth law of turbulence. Since Taylor,
the zeroth law has found many confirmations in several other experiments [32–35] and direct
numerical simulations (DNS) [36–41] in various geometries, but a derivation from the INSE
has yet to be found. The zeroth law therefore suggests that the mean energy dissipation rate of
turbulent flows remains finite even after the limit $\text{Re} \to \infty$ has been taken, which constitutes
one of the fundamental assumptions at the heart of Kolmogorov’s theory of 1941 (K41) [42].

After his discovery of the zeroth law, Taylor proposed a physical mechanism for energy
dissipation based on viscosity and Richardson’s cascade picture [18, 19]. Taylor used vortex
stretching to argue that by incompressibility, the stretching of vortex lines will be accompa-
nied by a reduction of the cross section of any vortex tube in which they are contained, leading
to an increase of $\omega^2$ through Kelvin’s theorem. Now, noting that the mean viscous energy
dissipation can be expressed as $\overline{\mathcal{D}}_\nu = \nu \overline{\omega^2}$ (where the overline denotes space averaging), it is easy to understand that if $\overline{\omega^2} \sim \nu^{-1}$ at small scales, the mean dissipated power $\epsilon = \nu \overline{\omega^2}$ becomes independent of the viscosity.

Onsager’s key remark was that energy dissipation may take place just as well without the
final assistance by viscosity, because Euler equations do not necessarily conserve energy if the
velocity field is not regular enough. Indeed, as we argued in section 2.1, solutions to the INSE which cannot satisfy any Hölder condition with an exponent $h > 1/3$ may produce an inertial dissipation independently of viscosity. Therefore, Onsager’s scenario can be viewed as an alternative to Taylor’s. An interesting point is that $h = 1/3$ in K41, which is also the maximum regularity condition compatible with a nonzero inertial dissipation.

2.2.2. Kármán–Howarth–Monin relation. A cornerstone of turbulence theory is provided by the Kármán–Howarth–Monin (KHM) relation [12, 43–45], valid for homogeneous turbulence, linking the energy injection per unit mass $\epsilon_t$ and velocity increments via

\[
\frac{1}{2} \partial_i \langle u_i (x) u_i (x + \ell) \rangle = \frac{1}{4} \nabla_i \langle \delta u_i (\ell) \delta u_i (\ell) \rangle + \nu \nabla_j \langle u_i (x) u_j (x + \ell) \rangle + \epsilon_t, \tag{21}
\]

where $\langle \rangle$ denotes statistical averaging, and we have dropped the dependence of $\delta u$ on $x$ by homogeneity. In equation (21), $E (\ell) = \langle u_i (x) u_i (x + \ell) \rangle$ is a measure of the kinetic energy at scale $\ell$. It is interesting to note that taking the statistical average of equation (7) and integrating over space, we get the following equation

\[
\frac{1}{2} \partial_\ell \int d\xi G_\ell (\xi) E (\xi) - \epsilon_t = - \frac{1}{4} \int d\xi \nabla_i G_\ell (\xi) \langle \delta u_i (\xi) \delta u_i (\xi) \rangle + \nu \int d\xi \nabla_j G_\ell (\xi) E (\xi). \tag{22}
\]

In order to obtain equation (22), we have assumed that the energy input is provided by boundary conditions. Since the global contribution of the divergence of the energy current in equation (7) can be reduced to the flux of $J$ at the boundaries, we therefore get that $\int \langle \partial_\ell J_\ell \rangle = - \epsilon_t$. As a consequence, one recognizes in equation (22) a weak formulation of the homogeneous KHM relation, which can also be considered as the average over a sphere of radius $\ell$ of the KHM relation. Now if we relax the conditions on the test function $G$ that we imposed in section 2.1, we see that taking $G_t = \exp (k \cdot x)$ with $k = \ell / \ell_0^2$ in equation (22) leads to the classical energy budget in Fourier space, where $\int \langle E (\ell) \rangle = E(k)$ is the energy density at wavenumber $k$. $\int \langle E^2 (k) \rangle = \nu k^2 E(k)$ is the viscous energy dissipation, and $\int \langle \Pi^\text{FR} \rangle = \Pi (k)$ is the scale-to-scale energy transfer rate.

$\Pi^\text{FR}$ therefore appears in equation (7) as a local expression of the scale-to-scale energy transfer of the KHM relation which is valid even when the flow is anisotropic, inhomogeneous, and when $u$ is not differentiable. This constitutes the main difference with its counterpart in equation (21). However, it was shown in [20] that assuming homogeneity, both terms have the same small-scale limit. Equation (7) can then be viewed as a generalization of equation (21) to inhomogeneous flows, therefore making the link with Onsager’s conjecture.

2.2.3. Practical implementation and Noise issues. The practical applicability of the KHM relation to turbulence relies on the fact that the statistical average of the third order structure function $\langle \delta u \delta u \delta^2 u \rangle$ is smooth enough to be differentiable. This is often the case if the turbulence is locally homogeneous, and if the experimental noise is isotropic, Gaussian and not correlated to the velocity measurements, as is often the case in the absence of systematic errors. In such a case, the measured velocity increments can be simply written as $\delta u_{\text{meas}} = \delta u + \alpha$, where $\delta u$ is the true velocity increment and $\alpha$ is the noise such that for any $i, j, k = 1, 2, 3$, $\langle \alpha_i \rangle = 0$ and $\langle \alpha_i \alpha_j \rangle = N^2 \delta_{ij}$, where $N$ is the noise amplitude. Since we further have

\[
\delta u_{\text{meas}} \delta u_{\text{meas}} = \delta u \delta u + \alpha \delta u + 2 \alpha \delta u \alpha + \alpha^2 = \delta u \delta u + \alpha \delta u + \alpha \alpha + \alpha \alpha,
\]

(23)
we get by statistical averaging
\[
\langle \delta u_{\text{meas}} | \delta u_{\text{meas}} \rangle^2 = \langle \delta u | \delta u \rangle^2 + 3N \langle \delta u \rangle.
\] (24)

If the velocity field is locally homogeneous then \( \langle \delta u \rangle = 0 \), so that all the noise contribution has been averaged out and there is no noise amplification introduced by taking the divergence. In the same way, if the noise has no spatial correlation, the statistical average guarantees that the noise contribution is averaged out in \( \langle E(\ell) \rangle \), so that it can be differentiated twice without noise amplification. This means that both the energy transfer and the dissipation term in the KHM relation can be computed with minimal noise from homogeneous, experimental fields.

The weak formulation ensures that this property is transferred in the computation of local instantaneous energy transfers via \( \Pi_{\text{DR}}^{\ell} \) and of the dissipation term \( \mathcal{D}_\nu^{\ell} \), in areas where the turbulence is homogeneous. Indeed, the gradient is not applied directly to the velocity increments, but rather on the smooth test function, preceded by a local angle averaging. The latter plays a similar role to statistical averaging for isotropic noise. The convolution with the derivative of the smoothing function further guarantees no experimental noise amplification. There is no additional noise induced by this procedure if one recognizes that the volume integrals performed in \( \Pi_{\text{DR}}^{\ell} \) and \( \mathcal{D}_\nu^{\ell} \) can be simply done via either continuous wavelet transform, or direct and reverse fast Fourier transforms and derivation of the smoothing function by multiplication in Fourier space, which can be computed analytically to avoid discretization effects. This robustness with respect to noise makes the quantity \( \Pi_{\text{DR}}^{\ell} \) a very interesting tool to localize potential singularities in both space and time, as we discuss in section 3.1. Note finally that the expression of \( \Pi_{\text{DR}}^{\ell} \) is very suitable for its implementation from experimental PIV measurements: it involves only velocity increments, which are easily computed from the velocity field data obtained by such technique.

2.2.4. Euler singularities versus Navier–Stokes singularities and the multifractal model. There are evidences coming from DNS that turbulent velocity fields admit a local scaling symmetry through the existence of a continuous set of scaling (Hölder) exponents \( h(x) \), with the most probable exponent close to 1/3 [24, 25]. These exponents can be defined as
\[
h(x) = \lim_{\ell \to 0} \frac{\ln |\delta u(x, \ell)|}{\ln(\ell/L)},
\] (25)

where \( L \) is a characteristic integral length of scale. These points correspond to the location where the scaling symmetry of the Euler equations \((t, x, u) \to (\lambda^{1-h} t, \lambda x, \lambda^h u)\) is locally satisfied [12], which means that the definition in equation (25) is valid under the assumption that \( \nu \to 0 \).

It can be seen that the above definition of \( h \) has a mathematical interest only for \( 0 \leq h \leq 1 \). However, it might be that this condition becomes too restrictive for practical purposes, in which case another definition should be come up with. As a matter of fact, there are several ways of doing so, and a discussion is provided in [29]. In particular, using wavelet coefficients, the definition of \( h \) can be extended to \( h < 0 \), which takes power-law blow-ups of the velocity field into account. Such blow-ups would then be identified as possible singularities of the Euler equation.

In the multifractal model of turbulence [46], it can be shown that the Hölder exponent at scale \( r \), defined as
\[
h(x, \ell) = \frac{\ln |\delta u(x, \ell)|}{\ln(\ell/L)},
\] (26)
follows a large deviation property [29]

\[ \text{Prob} \{ h(x, \ell) = h \} \sim \left( \frac{\ell}{L} \right)^{C(h)}, \]

(27)

where \( C(h) \) formally corresponds to the codimension of the set where the local Hölder exponent at scale \( \ell \) is equal to \( h \). Multifractal analysis of DNS or experimental data proved that the most probable exponent is \( h = 1/3 \) with \( C(1/3) \approx 0 \) [24, 25].

If we now consider a flow with finite viscosity, we have seen that the local energy balance at scale \( \ell \) is provided by equation (7). For a flow following locally \( \delta u(x, \ell) \sim \ell^h \), we have \( \Pi_{\text{DR}}^\ell \sim \ell^{3h-1} \) and \( \mathcal{G}^\ell_{\nu} \sim \nu \ell^{2h-2} \). These two terms balance at a scale \( \eta_h \sim \nu^{1/(1+h)} \). \( \eta_h \) thus appears as a fluctuating cut-off which depends on the scaling exponent and therefore on \( x \).

This is the generalization of the Kolmogorov scale \( \eta_{1/3} = (\nu^3/\epsilon)^{1/4} \), and was first proposed in [47]. As a consequence, \( \eta_h \) corresponds to the scale at which any possible Euler singularity of exponent \( h \) is regularized by viscosity. Above \( \eta_h \), \( \delta u(x, \ell) \sim \ell^h \) and energy is transferred towards small scales via \( \Pi_{\text{DR}}^\ell \), until \( \ell = \eta_h \) is reached, where \( \Pi_{\text{DR}}^\ell \sim \epsilon (\eta_h/L)^{3h-1} \). Below \( \eta_h \), the flow is regularized by viscous forces and \( \delta u(x, \ell) \sim \ell \) so that \( \Pi_{\text{DR}}^\ell \) decreases to 0 like \( \ell^2 \), kinetic energy being dissipated into heat by viscosity. As a consequence, if \( -1 < h \leq 1/3 \), Onsager’s scenario can only occur in the absence of viscosity. For this reason, we call such solutions dissipative Euler quasi-singularities. A noticeable exception comes from the case \( h = -1 \), for which \( \eta_{-1} = \lim_{\nu \to 0} \frac{\nu}{\epsilon} \) which is zero for any finite Reynolds number. For this exponent, there is no possibility of regularization by viscosity (1/\( r \) is a zero mode of the Laplacian), so that \( h = -1 \) might correspond to a Navier–Stokes singularity which would dissipate energy at infinitely small scales, following Onsager’s scenario. This is in agreement with the work of Cafarelli et al [15] who showed that if a singularity appears at some point in spacetime, which we denote \( (X_s, T_s) \), then at \( t = T_s, |u| \to \infty \) at least like \( |x - X_s|^{-1} \) when \( x \to X_s \).

The question now is: provided that such singularities actually occur, do they have a nonzero contribution to the total energy dissipation? The answer to this question depends on the value of the codimension \( C(-1) \). Indeed, the total contribution to the energy transfers for a given \( h \) scales like \( \Pi_{\text{DR}}^\ell \sim \ell^{3h-1+C(h)} \). We see that for \( h = -1 \), it is necessary to have \( C(-1) = 4 \) for \( \Pi_{\text{DR}}^\ell \) to be finite as \( \ell \to 0 \). This is in agreement with the well-known result of Cafarelli et al [15], who showed that the singular set of the INSE, if it exists, has a zero one-dimensional Hausdorff measure. More discussions on this matter are provided in [29].

2.2.5. Energy transfers. In the multifractal picture, the maximum amount of energy transfers depends on the local Hölder exponent: for \( 1/3 < h < 1 \), the energy transfers generally decrease as \( \ell \to 0 \), so that it typically never exceeds \( \epsilon \). This corresponds to non-dissipative Euler quasi-singularities. For \( h < 1/3 \), the energy transfers increase with scale until \( \ell \approx \eta_h \), so that they can reach large values \( \epsilon (\eta_h/L)^{3h-1} \gg \epsilon \), even below the Kolmogorov scale \( \eta = \eta_{1/3} \). Therefore, it appears possible to track possible Euler quasi-singularities or even Navier–Stokes singularities \( (h = -1) \), by monitoring the energy transfers at or below the Kolmogorov scale, and looking for locations where it exceeds the global energy dissipation by a large fraction. The method of detection of singularities we present in section 3 relies on this remark. Moreover, using a steepest descent argument, it is possible to estimate at each scale the mean energy transfer due to all quasi-singularities as

\[ \Pi_{\text{DR}}^\ell \sim \ell^{\min \{3h-1+C(h)\}} \sim \nu^{C(3)-1}, \]

(28)
where \( \zeta(p) = \min_h [ph + C(h)] \) is the exponent of the \( p \)th order structure function, depending on the singularity distribution through the shape of \( C(h) \). In the K41 theory \( \zeta(3) = 1 \), so that \( \Pi_{\text{DR}}^\ell \) is constant over the inertial range.

3. Singularity detection through Duchon–Robert formula

3.1. Detection method

We have seen in section 2.1 that if the velocity is locally characterized by a scaling exponent \( h > -1 \), then the energy transfer \( \Pi_{\text{DR}}^\ell \) locally vanishes for scales much smaller than \( \eta h \). In this section, we will make use of the converse statement of this result, i.e. if locally at a certain scale \( \Pi_{\text{DR}}^\ell \) takes very large values, then the flow in the region where this is observed is a Navier–Stokes singularity (possibly with \( h = -1 \)) or a dissipative Euler-quasi singularity which has not yet been regularized. In the former case, the velocity field is not differentiable, which necessarily comes from a blow-up of the velocity field itself [9–11, 15]. However, there are several reasons why such singularities cannot be directly detected from experimental measurements. First of all, measurement systems inevitably have a coarse space and time resolution while blow-ups occur instantaneously at single points [15]. Furthermore, post-processing techniques which provide the output velocity field smooth the data by performing local averages and by considering very large velocities as spurious vectors which, in the end, are discarded. The key idea is therefore to track possible singularities through the behaviour of \( \Pi_{\text{DR}}^\ell \) as one comes across the dissipative scale \( \eta = \eta_{1/3} \). If \( \Pi_{\text{DR}}^\ell \) vanishes as one approaches or goes to smaller scales than \( \eta \), then we have only seen local energy transfers through scales [30], which is ultimately converted into heat by viscous frictions, as in the traditional Taylor view of turbulence. On the other hand, if \( \Pi_{\text{DR}}^\ell \) keeps a nonzero value larger than some threshold \( Q \) for \( 0 < \ell < \eta \), then we detect a structure connected to a dissipative Euler quasi-singularity or Navier–Stokes singularity. In general, we can expect that the larger the threshold \( Q \), the smaller the exponent \( h \) we probe. For fixed viscosity and decreasing \( \ell \), we may even expect that arbitrary large values of \( Q \) only correspond to genuine Navier–Stokes singularities.

The only adjustable parameter in our detection method is the threshold \( Q \). A natural choice for \( Q \) is to take

\[
Q(\ell) = Q \sigma_{\text{DR}}(\ell),
\]

where the \( \sigma_{\text{DR}} \) denotes the standard deviation of \( \Pi_{\text{DR}}^\ell \). \( Q \) is therefore related to the quantile of the distribution of quasi-singularities [48]. For example, if \( Q = 10 \), we select events with an amplitude 10 times larger than the expected deviation from the spacetime average of \( \Pi_{\text{DR}}^\ell \). With \( Q = 100 \), we select more extreme quasi-singularities, which represent in general very rare events, presumably closer to the case \( h = -1 \) (Navier–Stokes singularities). In extreme value theory, there is no general rule as to what quantile should be used in order to consider an event as extreme. The most common choice when the events are normally distributed is to take \( Q = 3 \). In the rest of the paper we use \( Q = 3 \).

In all our computations, we have used a spherically symmetric function of \( r \) given by

\[
G(r) = \begin{cases} \frac{1}{N} \exp \left( -\frac{1}{1-r^2/4} \right) & \text{for } 0 \leq r \leq 2, \\ 0 & \text{otherwise}, \end{cases}
\]

where \( N \) is a normalization constant such that \( \int dr \, G(r) = 1 \). \( G \) has a compact support and satisfies the properties given in section 2.1.
3.2. Implementation

We illustrate our detection method using experimental velocimetry measurements. The data are TPIV measurements performed inside a boundary layer of a wind tunnel located at the Laboratoire de Mécanique de Lille, France. A sketch of the experimental set-up is displayed in figure 1 along with a typical instantaneous frame in a plane orthogonal to the mean flow. The test section of the wind tunnel is 1 m high, 2 m wide and 20 m long. The boundary layer...
thickness can reach up to 300 mm and the Reynolds number $R_\theta$ based on the momentum thickness is $R_\theta = 8000$, with a wall region of around 40 mm. The TPIV system is composed of six high-speed cameras recording the flow into a volume normal to the wall (see figure 1). The investigation volume is $5 \times 45 \times 45 \text{ mm}^3$ and, in the end, we get the three components of the velocity field on a grid of size $5 \times 67 \times 67$. Note that for this data, the resolution (grid spacing) is $\Delta x = 0.7 \text{ mm}$ while the Kolmogorov scale is of the order of $\eta \approx 0.35 \text{ mm}$. Therefore, we will be able to test the DR criterion at scales close to the dissipative scale. Let us finally make a small remark about the inertia of the particles. The wind tunnel was operated in a close-loop configuration with a free stream velocity of $3 \text{ m s}^{-1} \pm 0.5\%$ and a temperature of $15 \pm 0.2 \degree C$. The whole flow was seeded with polyethylene glycol smoke, which generates particles with a size of the order of $1 \mu m$. We can therefore compute their Stokes number which is $S_t \approx 4 \times 10^{-4}$. As a consequence, we have between two and three orders of magnitudes before the inertia of the particles becomes appreciable. Since we have also $S_t \approx \sqrt{\epsilon}$, this will happen in regions where $\epsilon$ is at least $10^4$ times larger than its average.

An example of variation of $\Pi_{\ell}^{DR}(u)/\sigma_{DR}$ as a function of scale $\ell$ and position $x$ in a plane orthogonal to the mean flow is provided in figure 2. In this figure, the scale is expressed in units of the Kolmogorov scale $\eta$. For scales $\ell \gtrsim 8\eta$, the topology of the ratio $\Pi_{\ell}^{DR}(u)/\sigma_{DR}$ does not vary much. This range of scales represent the end of the inertial range where $\Pi_{\ell}^{DR}$ captures the cascade of energy [30]. On the other hand, as we reach the dissipative range, i.e. $\ell \lesssim 8\Delta x$, $\Pi_{\ell}^{DR}(u)/\sigma_{DR}$ changes topology. We see that $\Pi_{\ell}^{DR}$ does not vanish, but instead remains larger than some threshold $Q$, which in several frames is found to be $Q = 10$, at localized areas which we identify as possible quasi-singularities with $h \leq 1/3$.

As explicitly written in equation (29), $\sigma_{DR}$ depends on the scale $\ell$. This can be seen on figure 3 which displays the spacetime probability distribution of $\Pi_{\ell}^{DR}$ in the $XZ$-plane studied in figure 2(a), in the stationary regime at three different scales (the same as in figure 2(a)). We observe that the statistics of $\Pi_{\ell}^{DR}$ is strongly non-Gaussian with very large tails [49]. It can be checked from these distributions that as $\ell$ is decreased, the spacetime average as well as the standard deviation of $\Pi_{\ell}^{DR}$ increases. As a consequence, we obtain distributions with wider

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure3.png}
\caption{Spacetime probability density distribution of the Duchon–Robert (DR) transfers $\Pi_{\ell}^{DR}$ at the three different scales studied on figure 2(a). The blue curve represents the smallest scale, and the red one the largest.}
\end{figure}
tails at smaller scales, and we detect more extreme events corresponding to possible quasi-singularities. In the three cases displayed on figure 3, it can be seen that the distributions are slightly skewed towards positive values, which allows the spacetime average of $\Pi_{\text{DR}}$ to remain positive, in agreement with [30].

### 3.3. 2D versus 3D detection

In principle, our method of detection requires the input of the three components of the velocity field in a volume, i.e. requires data from TPIV. In practice, some PIV systems are only stereoscopic, giving access to the three components of the velocity field on a plane only, but allowing for very long statistics. Since, in this case, velocity increments along one direction of space cannot be computed, this raises the question of whether the DR criterion is still able to detect quasi-singularities from SPIV data, or does the absence of the third direction lead to the detection of spurious structures which would disappear if the full 3D computation were to be performed? To answer this question, let us define a new quantity based on the inertial dissipation $D_{I}$, which is built from the three components of the velocity increments on a two dimensional plane

$$D_{I}^{2D}(u) \stackrel{\text{def}}{=} \lim_{\ell \to 0} \frac{1}{4} \int_{S} dr \partial_{i} G_{\ell}(r) \cdot \delta^{2D} u_{i}(r) \left| \delta^{2D} u(r) \right|^{2},$$

(31)

where $\delta^{2D} u(r) = u(x^{2D} + r^{2D}) - u(x^{2D})$, $x^{2D}$ and $r^{2D}$ being the projection onto the plane of measurements of the 3D coordinates. We now argue that areas where the full field $D_{I}(u)$ is zero are also areas where $D_{I}^{2D}(u)$ is zero, thus proving that no spurious singularities are detected in SPIV data.

To prove this, we note $B_{\ell}(x)$ is the ensemble of all the velocity increments of maximum size $\ell$ around a point $x$ (which is located in the plane of measurement), and $S_{\ell}(x)$ the subset of $B_{\ell}(x)$ of velocity increments with zero component in the direction perpendicular to the plane of measurement. Let us further denote $S$ the area of $S$, and $V$ the volume of $V$, and we define

$$\int_{S} dr \left| \nabla G_{\ell}(r) \right| = \frac{C_{G}}{\ell},$$

$$\int_{V} dr \left| \nabla G_{\ell}(r) \right| = \frac{D_{G}}{\ell}.$$

(32)

we have from Cauchy–Schwarz inequality

$$\left| \Pi_{\text{DR}}^{2D}(u) \right| \leq \int_{S} dr \left| \nabla G_{\ell}(r) \right| \int_{S} dr \left| \delta^{2D} u(r) \right|^{3},$$

$$\leq \frac{C_{G}}{\ell} \left( \sup_{S_{\ell}} \left| \delta^{2D} u(r) \right| \right)^{3} S,$$

$$\leq \frac{C_{G}}{\ell} \left( \delta u(x, \ell) \right)^{3} S,$$

(33)

with $\delta u(x, \ell) = \sup_{B_{\ell}} \left| \delta u(r) \right|$ (see section 2.1). On the other hand, we have also

$$\left| \Pi_{\text{DR}} \right| \leq \int_{V} dr \left| \nabla G_{\ell}(r) \right| \int_{V} dr \left| \delta u(r) \right|^{3},$$

$$\leq \frac{D_{G}}{\ell} \left( \delta u(x, \ell) \right)^{3} V.$$

(34)
Now, if $\delta u(x, \ell) \sim \ell^h$ as $\ell \to 0$, then $\left( \sup_{\|r\|} |\delta u(r)| \right)^3 = O(\ell^3 h)$, so that both SPIV and TPIV estimates decay to zero for $h > 1/3$. Therefore, the detection of dissipative Euler quasi-singularities via extreme events of $|\Pi_{\text{DR}}^\ell(u)|$ does not introduce any spurious structures which would disappear when performing the full 3D computation. However, we cannot detect maxima corresponding to increments lying only on the $y$-direction from SPIV data. It is then sufficient to use the criterion based on $\Pi_{\text{DR}}^\ell$, but it is not a necessary condition.

An illustration of this result can be provided by an application to our experimental data. In such a case, there is a strong streamwise mean flow and singularities are more likely to occur in the direction orthogonal to this plane. We thus choose $y$ as the streamwise direction and $z$ as the orthogonal direction. Figure 4 shows a comparison between two instantaneous maps of the Duchon–Robert (DR) criterion computed from both SPIV and TPIV data. (a) Map of the DR energy transfers $\Pi_{\text{DR}}^{\ell,3D}$ and (b) map of the DR energy transfers $\Pi_{\text{DR}}^\ell$ (normalized by their standard deviations). The results are displayed in the plane $y = 0$ orthogonal to the streamwise direction for the same data as in figure 2. The two orthogonal lines on map (b) represent the two planar cuts displayed on figure 5.

Figure 5. Instantaneous maps of the Duchon–Robert (DR) energy transfers, in the two planes represented by black lines on figure 4, normalized by their space-time averages. (a) shows a planar cut in an (XY) plane and (b) shows a planar cut in a (ZY) plane for the same data as in figure 2. These maps allow us to see that the structures we detect appear to have a three-dimensional structure.

Now, if $\delta u(x, \ell) \sim \ell^h$ as $\ell \to 0$, then $\left( \sup_{\|r\|} |\delta u(r)| \right)^3 = O(\ell^3 h)$, so that both SPIV and TPIV estimates decay to zero for $h > 1/3$. Therefore, the detection of dissipative Euler quasi-singularities via extreme events of $|\Pi_{\text{DR}}^\ell(u)|$ does not introduce any spurious structures which would disappear when performing the full 3D computation. However, we cannot detect maxima corresponding to increments lying only on the $y$-direction from SPIV data. It is then sufficient to use the criterion based on $\Pi_{\text{DR}}^\ell$, but it is not a necessary condition.

An illustration of this result can be provided by an application to our experimental data. In such a case, there is a strong streamwise mean flow and singularities are more likely to occur in the direction orthogonal to this plane. We thus choose $y$ as the streamwise direction and $z$ as the orthogonal direction. Figure 4 shows a comparison between two instantaneous maps of the Duchon–Robert (DR) criterion computed from both SPIV and TPIV data. (a) Map of the DR energy transfers $\Pi_{\text{DR}}^{\ell,3D}$ and (b) map of the DR energy transfers $\Pi_{\text{DR}}^\ell$ (normalized by their standard deviations). The results are displayed in the plane $y = 0$ orthogonal to the streamwise direction for the same data as in figure 2. The two orthogonal lines on map (b) represent the two planar cuts displayed on figure 5.

Figure 5. Instantaneous maps of the Duchon–Robert (DR) energy transfers, in the two planes represented by black lines on figure 4, normalized by their space-time averages. (a) shows a planar cut in an (XY) plane and (b) shows a planar cut in a (ZY) plane for the same data as in figure 2. These maps allow us to see that the structures we detect appear to have a three-dimensional structure.
compare the DR criterion applied on SPIV and TPIV data via instantaneous maps of $\Pi_\ell^{2D}(u)$ (figure 4(a)) and $\Pi_\ell^{DR}(u)$ (figure 4(b)). Even though there are some differences between the two maps, it can be seen that both fields are qualitatively the same. This confirms that all areas where $\Pi_\ell^{2D}(u) \neq 0$ are also areas where $\Pi_\ell^{DR}(u) \neq 0$. In order to quantify the correlation between both maps, we have performed the computation of the Pearson’s coefficient $R$ of linear correlation between areas of high energy transfer in $\Pi_\ell^{2D}(u)$ and in $\Pi_\ell^{DR}(u)$. We find $R = 0.96$, where the threshold of $Q = 3$ has been used to define extreme events. The two fields are very well correlated, as expected.

Figure 5 displays two planar cuts at $z$ constant (a) and $x$ constant (b), as represented on figure 4(b). As described in [26], the velocity field is only available in a few planes along the streamwise direction. Here, we have only access to five of them. Therefore, the resolution of the flow is not as good along the $y$ direction as it is for $x$ and $z$. However, we can see that at the resolution of our PIV system, the structures we observe appear to be three-dimensional.

3.4. Complementary study: comparison with vorticity

It is interesting to compare areas where the DR energy transfers are high, with areas where vorticity is high for several reasons. First, areas of large vorticity are traditionally associated with coherent structures in turbulence. The role of such a coherent structure in the dynamics of turbulence is still an ongoing debate, but one may wonder whether they have a role to play in the genesis of singularities or quasi-singularities. Second, areas of large vorticity are usually used in numerical simulation of Euler equation to detect singularities, because of the Beale–Kato–Majda (BKM) criterion [50]. The BKM theorem states that if the velocity field $u$ along with any of its derivatives up to order at least three are square-integrable, it remains so until its blowup time $T_\ast$, obtained when the vorticity $\omega(x, t)$ satisfies

$$\int_0^{T_\ast} \|\omega(x, t)\|_\infty \, dt = \infty.$$ (35)
In particular, this means that for any \( t < T_{*} \), the total kinetic energy of the flow remains bounded. Now because of Sobolev embedding theorem (see [51]), the hypotheses of the BKM theorem imply that for \( t < T_{*} \), \( u(t) \) is Hölder continuous for any exponent \( h \) such that \( 0 < h \leq 1/2 \). As a consequence, there cannot be any inertial dissipation before \( T_{*} \). A necessary condition to observe such a dissipation is therefore that the vorticity becomes unbounded at the time where the singularity occurs. Hence, it makes sense to compare the DR and BKM criteria. Moreover, the correlation between regions of large vorticity and regions of large energy transfers may be used to trace areas where \( h > 0 \).

Finally, we have seen that in a locally homogeneous flow, the mean viscous dissipation is proportional to the mean enstrophy \( \overline{\omega^2} \). Such viscous dissipation overtakes the energy transfers as \( \ell \to 0 \) for any quasi-singularities \(-1 < h < 1/3\). Therefore, if any genuine singularity of Navier–Stokes exist, it is plausible that it exists in areas where the energy transfer is large, but the local enstrophy is still negligible. This would mean that any genuine Navier–Stokes singularity is uncorrelated to areas with very large enstrophy (if the flow is locally homogeneous).

For all these reasons, we provide a comparison between the results obtained from the DR criterion and the vorticity field. Let us look at figure 6, where maps of \( \Pi_{DR}^\ell(u) \) and \( |\omega(x,z)| \) (both normalized by their standard deviation) are displayed, using the same data as in figure 4.

First of all, we observe on figure 6(b) that the vorticity is almost zero everywhere, except for some areas where it is concentrated into thin filaments of high intensity. Moreover, comparing figure 6(a) with figure 6(b), it can be seen that areas where the structures of dissipation detected by the DR criterion are localized are also areas where the norm of the vorticity is high. In order to quantify how much both maps are related, we compute the Pearson’s coefficient \( R_y \) of linear correlation between areas where both criteria show intense events. We find \( R_y = 0.84 \), where the threshold of \( Q = 3 \) has been used to define extreme events. Therefore, we observe that areas of strong energy transfers in \( \Pi_{DR}^\ell(u) \) are correlated with areas of strong vorticity most of the time, presumably corresponding to dissipative quasi-singularities of Euler with \( h > 0 \). This is already an indication that they are more numerous than genuine singularities. In order to understand how many of the intense events of DR which are uncorrelated to vorticity are genuine singularities, we would need an alternative way to measure local Hölder exponents \( h < 0 \). This is the subject of an ongoing research.

Let us now investigate whether there still is a high correlation between the DR criterion and the vorticity field when using SPIV data. The maps are displayed on figure 7. In the case of SPIV data, the only component of the vorticity that we are able to reconstruct is the one orthogonal to the plane of measurement (here \( \omega_y \)). Therefore, the question we ask is: does the link between the enstrophy and DR criteria still exist when using SPIV data? Or, put another way, are areas of strong DR energy transfer also areas where \( \omega_y \) is high? Comparing both maps on figure 7, there indeed seems to be a correlation between both maps. We can quantify this correlation by once again computing the correlation coefficient \( R_y = 0.75 \). As a consequence, the relation between the energy transfer DR and enstrophy seems to hold well for this geometry, whether for TPIV or for SPIV data. However, there is no guarantee that it is still the same in other geometries.

4. Singularity detection through Eyink formula

A few years after the publication of [20], Eyink noticed that singularities may also cause a breakdown of Kelvin’s theorem [21–23], in the sense that in addition to a nonzero energy dissipation rate, they might also produce a nonzero rate of velocity circulation decay \( \Gamma_{\ell}(u) \) given by
\[
\frac{d}{dt} \Gamma_{\ell}(u) = \oint_{C} ds \cdot F_{\ell}(u),
\]
where
\[
F_{\ell}(u) = \frac{1}{\ell} \int_{V} dr \left[ \left( \delta u(r) - \int_{V} dr' G_{\ell}(r') \delta u(r') \right) \cdot \nabla G_{\ell}(r) \right] \delta u(r),
\]
and \(C\) is a contour advected by the fluid. \(F_{\ell}(u)\) is called the turbulent vortex-force. This is an important remark since Kelvin’s theorem plays an important role in Taylor’s vortex stretching mechanism for energy dissipation [18, 19, 23].

### 4.1. Detection method

We have seen in sections 2 and 3 that the velocity field \(u\) of a flow might develop singularities due to some internal mechanisms in the INSE, which are not fully understood. At the points in spacetime where this happens, \(u\) might however satisfy some Hölder continuity property with exponent \(h\). At points where \(h > 1/3\), no additional dissipation to viscosity occurs according to Onsager’s arguments. However, if \(h \leq 1/3\) an additional energy dissipation (or production) might appear [20, 23], causing kinetic energy to cascade through scales. Our detection method introduced in section 3 is based on the computation of this additional term in the energy balance at scale \(\ell\) and then track areas where it does not vanish with decreasing scale.

We introduce now a very similar detection method which is based on the observation that the turbulent vortex-force in (37) satisfies \(F_{\ell}(u) = O(\delta u(\ell)^2/\ell) = O(\ell^{2h-1})\) if \(\delta u(\ell) \sim \ell^{h}\) in the small scale limit, as discussed in [21–23]. Therefore, the computation of the turbulent vortex-force allows us to track dissipative Euler-quasi singularities or Navier–Stokes singularities with \(h \leq 1/2\), whereas the DR criterion only allows us to track the ones with \(h \leq 1/3\).

Moreover, just as for the DR term, this computation only involves velocity increments, which are easily accessible via PIV measurements. For the same reason mentioned in section 3.1,
a detection criterion based on circulation production is only a necessary but not sufficient one (since our PIV set-up is not space resolved). Keeping the same test function \( G \) as in equation (30), we can implement a detection method very similar to the one described in section 3, but based on another cascading quantity. Therefore, two questions arise. (i) Starting from our TPIV data and computing maps of \( \Pi^{\ell}_{\text{DR}} \) and \( \frac{d}{d\tau} \Gamma^{\ell}(u) \), are intense events in both cases well correlated? (ii) Are we able to detect areas where a strong circulation production is observed while the DR term is weak? This could mean the detection of non-dissipative Euler quasi singularities with \( 1/3 < h \leq 1/2 \).

4.2. Implementation of the method

The arguments which have been made in section 3.3 to show that it is enough to look for quasi-singularities from SPIV via energy transfers can be once again made here. Therefore, in the following, we will focus on SPIV data.

Let us first compare maps of \( \Pi^{\ell}_{\text{DR}}(u) \) (we drop the superscript ‘2D’) and \( \frac{d}{d\tau} \Gamma^{\ell}(u) \) in order to answer the first question. Maps of these two quantities (normalized by their standard deviation) are displayed on figure 8 for the same data set as in figure 4.

First of all, it can be observed that areas where \( \frac{d}{d\tau} \Gamma^{\ell}(u) \) is nonzero are organized in very thin filaments. In addition, figure 8(b) is more noisy than figure 8(a) even though the same procedure is applied in both cases, i.e. a derivative in scale is applied on the smoothing function, followed by a local angle averaging. There appears to be some correlation between the maps: in areas where \( \Pi^{\ell}_{\text{DR}} \) is strong, there always is some nonzero circulation decay. However, we observe that regions of largest rate of circulation decay are either shifted with respect to areas of strong dissipation, or exist in some areas where there is little energy transfers (see contours on figure 8(b)). Overall, the Pearson’s coefficient of linear correlation \( R_T \) between regions of strong events \( (Q = 3) \) in both fields is \( R_T = 0.85 \). We therefore obtain a good correlation...
between areas where both $\frac{d}{dt} \Gamma(u)$ and $\Pi_{\text{DR}}$ are strong, which is consistent with the possibility that Euler singularities may cause a breakdown of Kelvin’s theorem.

Figure 9 displays the spacetime probability distribution of $\frac{d}{dt} \Gamma(u)$ in the same XZ-plane studied up to now, in the stationary regime. Here again, we observe strongly non-Gaussian statistics with very wide tails, which confirms that $\frac{d}{dt} \Gamma(u)$ can be used as a criterion to detect possible singularities through scales. However, the fact that the maps of circulation are more noisy than the maps of dissipation makes their use less straightforward to detect quasi-singularities.

5. Discussion

In this paper, we have introduced two new methods based on the work of Duchon, Robert and Eyink [20–23], which allow for the local detection of dissipative Euler quasi-singularities or Navier–Stokes singularities in experimental flows. Both criteria assume the knowledge of spatial velocity increments only and are therefore easy to implement experimentally as well as numerically. The key idea behind their implementation is that velocity field in turbulent flows might lose some regularity while satisfying Hölder continuity conditions with an exponent $h \leq 1$ in the limit of small scales. If $h \leq 1/2$, a cascade of circulation might occur and Kelvin theorem breaks down. This cascade can be detected at larger scales provided that we are in the inertial range. In the same way, if $h \leq 1/3$, then a cascade of energy might occur which can also be detected in the inertial range. The first criterion that we introduced (DR criterion) focuses on these energy transfers, which are described by $\Pi_{\text{DR}}$ (see equation (7)).

From its probability distribution, we observed in section 3.2 that $\Pi_{\text{DR}}$ has a strongly non-Gaussian statistics, with very wide tails, in agreement with [49]. This indicates the existence of extreme events which might correspond to Euler quasi-singularity or genuine Navier–Stokes singularities. In addition, we saw that as the scale is decreased, the standard deviation of $\Pi_{\text{DR}}$ increases, which results in the tails of the distribution getting wider.

Furthermore, since Navier–Stokes singularities concern the blow-up of the velocity field, we expect to observe a very strong vorticity at the location of possible singularities. As a
consequence, we compared the DR criterion with the vorticity field, and found a good agreement between them, whether SPIV or TPIV data sets are considered.

We also showed analytically that to detect singularities, one does not need to have access to the whole velocity field inside a volume, but can instead look for them from stereoscopic particle image velocimetry (SPIV) data on a plane. This is confirmed by performing both 2D and 3D computations and comparing maps of the DR term $\Pi^{DR}(u)$ from TPIV measurements obtained inside the boundary layer of a wind tunnel [26]. Clearly, being limited to SPIV data means the information along a third direction are lacking meaning, and that quasi-singularities with structure in the third direction cannot be detected. In this flow, we observe that the computation of the DR term actually shows areas where it is nonzero, some of them being characterized by very strong (extreme) energy transfers through scales.

Finally, we investigated a second new method for the detection of singularities based on the possibility of a breakdown of Kelvin theorem at very large Reynolds numbers [21–23]. We showed that this method is well correlated with the DR criterion even though areas of intense energy transfers are sometimes shifted compared to areas of high rate of circulation. However, due to higher noise, this method is less reliable than the DR method, but it may allow for the detection of a wider range of singularities.

In the present paper, our detection methods were applied inside a boundary layer geometry, the resolution of our data being close to, but not exactly reaching, the dissipative scale. The fact that we detect areas with negative $\Pi^{DR}$ suggests that we observe energy transfers through scales [30], but not dissipation due to singularities. This is a strong indication that the Kolmogorov scale $\eta$ is not the smallest relevant scale for energy dissipation and that there might actually exist smaller scales at which dissipation takes place, as suggested by the multifractal picture of turbulence. To get stronger conclusions about the existence and topology of dissipative Euler quasi-singularities or Navier–Stokes singularities in experimental flows, we need measurements with a resolution smaller than the Kolmogorov scale. An attempt in that direction is made in [49]. We hope our work will help in providing experimental constraints on the properties of Navier–Stokes singularities as well as on corresponding suitable weak solutions.
