ABSTRACT

BACKGROUND AND PURPOSE: In addition to the 4 histopathologically defined entities of medulloblastoma, 4 distinct genetically defined subgroups have been included in the World Health Organization classification of 2016. The smallest subgroup is the medulloblastoma with activated wingless pathway. The goal of this study was to identify a typical MR imaging morphology in a larger number of pediatric patients with wingless pathway medulloblastoma.

MATERIALS AND METHODS: From January 2001 to October 2017, of 75 patients with histologically confirmed and molecularly subgrouped wingless pathway medulloblastomas recruited to the German Pediatric Brain Tumor (HIT) trials, 38 patients (median age, 12.8 ± 4.6 years at diagnosis; 24 [63.2%] female) had preoperative imaging that passed the entry criteria for this study. Images were rated by the local standardized imaging criteria of the National Reference Center of Neuroradiology. Additionally, a modified laterality score was used to determine tumor localization and extension.

RESULTS: Twenty-eight of 38 (73.7%) were primary midline tumors but with a lateral tendency in 39.3%. One extensively eccentric midline tumor was rated by the laterality score as in an off-midline position. Five tumors were found in the cerebellopontine angle; 3, in the deep white matter; and 2, in a cerebellar hemisphere. Leptomeningeal dissemination was rare (11.5%). In 60.5%, intratumoral blood-degradation products were found, and 26.3% showed cysts with blood contents.

CONCLUSIONS: According to our observations, wingless pathway medulloblastomas are not preferentially off-midline tumors as postulated in previous studies with smaller wingless pathway medulloblastoma cohorts. Dense intratumoral blood-degradation products and cysts with blood contents are frequently found and might help to differentiate wingless pathway medulloblastoma from other medulloblastoma subtypes.

ABBREVIATIONS: CMB = classic medulloblastoma; CPA = cerebellopontine angle; HIT = German abbreviation for brain tumor; LCMB = large-cell medulloblastoma (according to the World Health Organization classification of 2007); LS = laterality score; MB = medulloblastoma; SHH = sonic hedgehog pathway; WHO = World Health Organization; WNT = wingless-activated; WNT-MB = WNT-activated medulloblastoma

According to the revised WHO Classification of Tumors of the Central Nervous System of 2016,1 medulloblastoma (MB) is not considered a single tumor entity but represents several entities with different cells of origin, location, biology, genetic or (epi-)genetic alterations, histology, and clinical behavior. According to the concept of an integrated diagnosis in the World Health Organization (WHO) classification of 2016, medulloblastoma (MB) entities are defined by both histologic and molecular/genetic features, allowing a precise assignment of patients for risk-adapted stratification in current therapeutic studies and the comparison with results of study cohorts in the past. All MB entities correspond to WHO grade IV. For a definition of the histologic diagnosis, the tumors should be assigned to 1 of the 4 entities: classic (CMB), desmoplastic nodular, extensive...
nodularity, or large cell/anaplastic MB. Large-cell MB (LCMB) and anaplastic MB were separate histologic entities before 2016. Two in addition to these histologic entities, 4 genetically defined subgroups have been introduced by the WHO classification of 2016. Two subgroups are defined by their genetic pathway, wingless-activated (WNT) and sonic hedgehog–activated (SHH) MB, the latter with or without an accompanying TP53 mutation. The non-WNT/non-SHH subgroup is provisionally subclassified into group 3 and 4 medulloblastomas, which seem to be overlapping variants. WNT-MBs are characterized by activating mutations of CTNNB1, which encodes a central component of the WNT pathway or, alternatively, by inactivating mutations of APC, AXIN1 or AXIN2, leading to nuclear accumulation of β-catenin. Accounting for approximately 10% of all MBs, WNT-MBs form a small-but-distinct MB entity. In children, they show a significantly better progression-free survival and overall survival compared with other subgroups. In patients with WNT-MB younger than 16 years of age at diagnosis, a progression-free survival of 100% for 5 years has been observed.

Current therapy studies, such as the SIOP-PNET5 (NCT02066220) medulloblastoma trial, have implemented upfront genetic evaluations so that patients with low-risk WNT-MBs are eligible for radiation therapy reduction aimed at reducing late effects, with the therapy increasingly being adapted to the specific risk profile of each patient. Additionally, radiologic imaging signatures have become apparent for certain brain tumors and their underlying genetic profiles. The term “radiomics” is increasingly applied to describe the association between imaging phenotype and tumor genotype. A priori knowledge of the radiologic imaging phenotype can become clinically meaningful, for example, when it offers the neurosurgeons and neuro-oncologists a better preoperative estimation of the prognosis and risk of relapse of the tumor. Based on the principle of radiomics, our aim was to evaluate specific imaging characteristics of WNT-MB. Due to the large number of participating study sites, automated techniques of radiomics image analyses including algorithms of machine learning, were not included in this study.

Besides standard imaging characteristics, radiologic studies have mainly focused on correlations of tumor position and genetic information. A first radiologic subgroup analysis showed a preferential tumor location for WNT-MB in the cerebellopontine angle (CPA) and for sonic hedgehog-activated medulloblastoma (SHH-MB) in the cerebellar hemisphere. More recent studies with sample sizes of WNT-MB of n = 15, n = 16,14 and n = 17 yielded heterogeneous results with regard to tumor localization. The goal of the present study was to analyze structural MR imaging features according to defined MR imaging criteria in a large number of genetically determined WNT-MBs (n = 38) in children within the framework of the German Pediatric Brain Tumor (HIT) trials and the National Reference Center for Neuroradiology.

MATERIAL AND METHODS

Study Cohort

Cases were retrospectively collected from the data base of the National Reference Center for Neuroradiology (Department for Neuroradiology, Wuerzburg University Hospital) for the German Brain Tumor (HIT) trials, conducted in German-speaking countries of Europe. All patients were registered to the HIT-2000 trial (January 2001 to December 2011 [NCT00303810]), including participants of the German PNET 4 cohort from January 2001 to December 2007 [NCT01351870]), the HIT-2000 interim registry (recruiting January 2012 to December 2014 [NCT02238899]), the I-HIT-MED registry (recruiting since January 2015 [NCT02417324]), or the SIOP-PNET 5 MB trial (recruiting since June 2014 [NCT02066220]). Each patient or legal guardian signed an informed consent declaration when entering the study allowing the scientific evaluation of biologic and imaging data. All cases were centrally reviewed at the National Brain Tumor Reference Center of the German Society of Neuropathology and Neuroanatomy, Institute of Neuropathology, Bonn University. Patients were eligible if they had histopathologic and genetic classification data and preoperative cranial and spinal imaging.

FIG 1. A–C, and E, T2WI. D, T2-FLAIR. Examples for primary tumor positions in WNT-MB. The midline fourth ventricle (A), cerebellopontine angle (B), cerebellar hemisphere (C), midline cerebellar vermis (D), and periventricular deep white matter (E).
Histological diagnosis was made at inclusion into the trial according to the WHO classification valid at the time. Patients were diagnosed by a combination of histologic examination by immunohistochemistry and Sanger sequencing of exon 3 of CTNNB1. In case of negative CTNNB1 mutation, APC, AXIN1, and AXIN2 sequences were assessed additionally. Neuropathologic evaluation and CTNNB1 mutation analysis were supplemented by 450k DNA methylation microarray (Illumina, San Diego, California) if applicable. Where tissue was too scarce for analysis by methylation microarray, subgroup was assigned using the mass spectrometry–minimal methylation classifier assay in addition to immunohistochemistry and CTNNB1 mutation analysis. Where the initial work-up did not include prospective assessment of WNT activation, this was done during retrospective work-up as previously described. Patients were considered to have WNT-MB if molecular analysis confirmed a mutation in CTNNB1 or APC and/or assignment to the WNT-subgroup by methylation profiling or mass spectrometry–minimal methylation classifier.

### Imaging Analysis

All MR imaging datasets were assessed in consensus by 2 neuroradiologists dedicated to pediatric brain tumor imaging (M.W.-M. and A.S.). Multicenter data acquisition resulted in nonuniform MR imaging protocols, sequence technique, parameters, and field strength. Inclusion was possible with T2WI or T2-FLAIR and contrast-enhanced T1WI. The primary tumor location was determined as: cerebellar hemisphere, deep white matter, CPA, cerebellar vermis, or fourth ventricle (Fig 1). Deep white matter, cerebellar hemisphere, and CPA were rated as primary lateral positions. When the CPA was involved, the status of the fourth ventricle and the foramen of magendie was recorded additionally. Fourth ventricle and cerebellar vermis were defined as primary midline positions. Additionally, laterality of primary midline tumors was assessed according to a modification of the laterality score (LS) by Patay et al. Primary positions in the fourth ventricle or the cerebellar vermis were rated as midline (LS-0). Fourth ventricle or cerebellar vermis plus bilateral recess extension was rated as LS-0 as well. Midline tumors were rated as moderately lateralized in case of tumor extension into only the unilateral recess or bilateral recesses plus 1 CPA (LS-1). Extension into only the unilateral recess and further into the ipsilateral CPA was rated as heavily lateralized and off-midline (L-2).

Local standardized diagnostic parameters were supplemented and used for the imaging assessment. The tumor volume is calculated using the approximation of the ellipsoid volume formula \( V = \frac{4}{3} \pi ABC \) where \( A, B, \) and \( C \) are the maximum dimensions in the standard anterior-posterior, craniocaudal, and transverse planes. The largest diameter of the perifocal edema was measured in centimeters. Signal intensity and homogeneity of the tumor were assessed in comparison with gray matter on T2WI and T1WI without contrast enhancement. Intensity and percentage of enhancing volume after gadolinium application were estimated. The contrast-enhancing area of the tumor mass is mainly diffuse, whereas the rating was subjective in approximately percentages (0%–25%, 26%–50%, 51%–75%, 76%–100%).

Hydrocephalus was rated as slight, moderate, and severe (slight meaning only visible dilation of the ventricles, moderate showing CSF pressure caps, and severe showing pressure caps

### Molecular Analysis

Histological diagnosis was made at inclusion into the trial according to the WHO classification valid at the time. Patients were diagnosed by a combination of histologic examination by
with compression of the sulci at the vertex). Fluid of intratumoral cysts was compared with the signal of CSF and defined as: as bright as CSF and brighter than CSF, presence of blood-degradation products like methemoglobin or hemosiderin was noted. Leptomeningeal dissemination was assessed only by MR imaging according to the classification of Chang et al.\textsuperscript{21} Cranial dissemination was rated as M2; spinal dissemination, as M3; and cranial dissemination was assessed only by MR imaging and classified all tumors as WNT. There were 2 cases without Sanger sequencing: One was categorized as WNT-activated by mass spectrometry–minimal methylation classifier assay and the other one by 450k methylation microarray. In 1 tumor, analysis was negative for the CTNNB1 mutation but was classified as a WNT subgroup by 450k methylation microarray analysis, and additionally, a copy-neutral loss of heterozygosity within the chromosome arm 5q (APC) and a R213* mutation in the APC gene were identified. One patient was diagnosed as having WNT-MB based on tissue of tumor recurrence; here, CTNNB1 mutation and WNT-activation in 450k methylation microarray were detectable.

An overview of the MR imaging features is shown in Table 1, and primary tumor localization and extension are presented in Table 2. Twenty-eight tumors were primarily located in the midline position. Fourteen of 25 microarray was supplemented and classified all tumors as WNT. There were 2 cases without Sanger sequencing: One was categorized as WNT-activated by mass spectrometry–minimal methylation classifier assay and the other one by 450k methylation microarray. hydrocephalus. Fifteen (39.5%) patients had no hydrocephalus at diagnosis. Tumor signal intensity in T2WI compared with the supratentorial cortex was predominantly isointense (54.1%) to hypointense (35.1%). Only 4 tumors (10.8%) were hyperintense in comparison with the signal intensity of the cortex on T2WI. In 1 child, no standard T2 sequence but a FLAIR sequence was available for evaluation. Thirty-one (83.8%) tumors showed inhomogeneous signal on T2WI; only 6 of 37 (16.2%) showed homogeneous signal. On T1WI, the signal intensity was hypointense in 27 of 38 (71.1%) tumors. Eight (22.2%) tumors showed an isointense signal, and only 1 tumor (2.8%) showed a completely hyperintense signal. Two patients had no standard unenhanced T1WI at diagnosis. Signal on T1WI was homogeneous in 41.7% and inhomogeneous in 58.3%. Thirty-six of 38 (94.7%) WNT-MBs showed contrast enhancement in 76%–100% of the tumor volume; only 1 WNT-MB showed an enhancing volume of 26%–50%, and 1 WNT-MB, 26%–50%. Signs of bleeding in T1WI, T2WI, or susceptibility-weighted images were found in 23/38 (60.5%).

In 18 of those cases, susceptibility-weighted images such as SWI or T2* sequences had been acquired. Sixteen of 18 (88.9%) susceptibility-weighted images showed iron content. Five of 16 MBs showed iron deposition in >50% of the tumor mass. The extension of perifocal edema ranged from 0 to 2.6 cm (mean, 0.66 ± 0.62 cm). Twenty-seven of 38 (71.1%) MBs showed perifocal edema. Tumor volume ranged from 2.68 to 68.59 cm³ (mean, 27.79 ± 16.87 cm³). LCMBs are usually significantly smaller than other histologic MB types (mean, 15 cm³) as described previously.22 By means of this value from the literature as a cutoff between large and small tumor sizes, 10 of 40 WNT tumors were small (range, 2.68–12.77 cm³); all of them presented with classic histology. The 2 large-cell/anaplastic MBs had volumes of 29.81 and 46.39 cm³. Leptomeningeal dissemination at diagnosis was assessable in 35 patients and was positive in 11.5% (4 of 35). One patient showed cranial dissemination (M2), 2 had cranial and spinal dissemination (M2 + 3), and 1 patient showed isolated spinal dissemination (M3). All 4 disseminated WNT-MBs showed classic histology in the primary tumor.

**DISCUSSION**

To our knowledge, this series represents the largest cohort of WNT-MBs analyzed for characteristic MR imaging features thus far. Our results show that the preferred primary position of our WNT-MBs is the midline fourth ventricle or vermis in 28 of 38 (74%). Perreault et al were the first to report that WNT-MBs are characterized by an off-midline position in 75% (3 of 4 were located in the CPA or cerebellar peduncle), leading to a positive predictive value of 100% for this tumor site. In our cohort, only 5 of 38 (13%) WNT-MBs had their epicenter in the CPA; altogether, only 26% were primarily located in an off-midline position. This is much lower compared with earlier study results.12–14 Gibson et al indicated that WNT-MBs arise in the lower rhombic limb from progenitor cells of nuclei in the dorsal brain stem and all 6 WNT-MBs in this publication were reported as midline tumors. Similarly, Lastowska et al found 5/6 and Teo et al described 5 WNT-MBs in a midline position. On the basis of the hypothesis of Gibson et al on the individual tumor origin, the pathways of extension were evaluated in more detail. With a self-defined score, Patay et al emphasized the lateralized position of WNT-MBs (50% off-midline position). We support the conclusion of Patay et al that WNT-MBs are paramedian midline tumors, describing a lateralized position in 22/38 tumors in our cohort. However, a purely CPA localization (5 of 38) seems to be much rarer than previously noted.12 The primary midline position is in line with the hypothesis that WNT-MBs arise from the dorsal brain stem and grow within the CSF spaces. Notably, the fourth ventricle may be the preferred pathway of tumor growth because it offers the least resistance. With only 3 tumors having their epicenter in the deep white matter surrounding the fourth ventricle in our study, this localization was significantly less frequent compared with that in previous studies (8% versus 20%).13

While Perreault et al and Mata-Mbemba et al assigned a cerebellar hemispheric origin as highly predictive of SHH-activated MB, we found 2 WNT tumors located in the cerebellar
hemisphere. However, both tumors were large, rendering the definition of their origin in differentiation between hemisphere and paraventricular white matter to be challenging. These different tumor locations in our cohort and partially divergent results compared with the previous studies question whether the off-midline or midline position has any useful diagnostic predictive value. The 4 genetic subgroup model was refined by Taylor et al in 2012 and has been updated recently. Further refined definitions of substructures within the 4 WHO entities of MB may be expected. The existence of such substructures might be a possible cause for the heterogeneity of the epicenter of the tumor in our study and the divergent reports of the typical location of WNT-MBs in previous studies.

The children in our cohort were older than 4 years of age; this matches previous observations that WNT-MBs do not typically occur in early childhood. Most WNT-MBs in our cohort were histologically CMBs, but there were single other histologic types (large-cell/anaplastic MB, n = 2) as well. The fact that WNT-MBs are not exclusively CMBs has been reported previously. Our cohort contained 1 tumor corresponding to an LCMB (according to the WHO classification of 2007). This is in accordance with Ellison et al and Kool et al reporting 2% LCMBs among their group of WNT-MBs. With a mean tumor volume of 15 cm³, LCMBs have been described as significantly smaller than other histologic types of MB. Most interesting, 10 CMBs in our cohort had a tumor size of >15 cm³, and the only LCMB showed double that size. In our cohort, 11.5% of patients showed a macroscopic leptomeningeal dissemination at diagnosis. This percentage is similar to the numbers reported in studies on neuropathology but higher than in previous radiologic studies.

We found a female predominance, which is contrary to that in the cohort of Patay et al. The female predominance in our cohort should be considered with caution due to the small cohort size in comparison with publications that have recorded the demographic data of significantly more WNT-MBs and found no predominance of male or female.

MBs are tumors of high cellularity for which a lower signal on T2WI can be expected. In our cohort, WNT-MBs were primarily iso- to hypointense on T2WI. The comparatively low T2 signal is useful to differentiate MBs from pilocytic astrocytomas and, to a lesser extent, also from ependymomas. Inhomogeneous signal on T2WI and the moderate-to-strong contrast enhancement do not directly compare the results with those of other MB subgroups. Due to the multicenter principle, we assessed imaging data from MR imaging scanners at different magnetic field strengths and sequence techniques. Thus, heterogeneity of imaging data could not be completely controlled.

CONCLUSIONS

WNT-MBs are found predominately in the fourth ventricle. However, a certain laterality can be noted by their hypothetic point of origin and possible growth characteristics. However, hemispherically positioned WNT-MBs and leptomeningeal dissemination can occur and may not be used as a criterion to exclude WNT-MB. Dense intratumoral blood-degradation products and cysts with blood contents are frequently found and might help to differentiate WNT-MBs from other MB subtypes.

ACKNOWLEDGMENTS

We thank Dr D. Engel for her support in manuscript correction.
