Supporting Information

ABSTRACT: Light-oxygen-voltage (LOV) domains are increasingly used to engineer photoresponsive biological systems. While the photochemical cycle is well documented, the allosteric mechanism by which formation of a cysteinyl-flavin adduct leads to activation is unclear. Via replacement of flavin mononucleotide (FMN) with 5-deazaflavin mononucleotide (5dFMN) in the Aureochrome1a (Au1a) transcription factor from Ochromonas danica, a thermally stable cysteinyl-5dFMN adduct was generated. High-resolution crystal structures (≤2 Å) under different illumination conditions with either FMN or 5dFMN chrophores reveal three conformations of the highly conserved glutamine 293. An allosteric hydrogen bond network linking the chromophore via Gln293 to the auxiliary A’α helix is observed. With FMN, a “flip” of the Gln293 side chain occurs between dark and lit states. 5dFMN cannot hydrogen bond through the C5 position and proved to be unable to support Au1a domain dimerization. Under blue light, the Gln293 side chain instead “swings” away in a conformation distal to the chromophore and not previously observed in existing LOV domain structures. Together, the multiple side chain conformations of Gln293 and functional analysis of 5dFMN provide new insight into the structural requirements for LOV domain activation.

Light-oxygen-voltage (LOV) photoreceptors are members of the Per-ARNT-Sim (PAS) superfamily of proteins that act as blue-light-sensing modules, mediating a wide range of processes, including phototropism, circadian rhythms, and stress responses. The modular arrangement of sensory LOV domain proteins and effectors found in nature has inspired many synthetic designs. Such engineered proteins exhibit varying levels of photosensitivity, which can be partly attributed to the incomplete understanding of the mechanisms of allosteric control employed by natural LOV domains over effector modules. To fully exploit the photochemical potential of LOV domains for engineered systems, a comprehensive picture of the structural determinants of allostery is needed. The structure of the LOV domain core is highly conserved, comprising a flavin chromophore binding site composed of a five-stranded, antiparallel β-sheet with ancillary helices. Blue-light absorption results in the formation of reversible covalent adducts between the flavin isoalloxazine ring (C4a) and the sulhydryl side chain of a conserved cysteine residue (Figure 1A). Flanking A’α (N-terminal) and Jα (C-terminal) helices act to relay photochemically induced changes in the LOV domain to associated effector modules. Although the core LOV domain is structurally conserved, several different mechanisms of signal transduction are known. Mechanisms include Jα helix unfolding to release effector domains in Arabidopsis thaliana phototropin 1 LOV2 (AtLOV2), Jα rotation and effector domain rearrangement in Bacillus subtilis YtvA (BsYtvA) and dimerization in Neurospora crassa vivid (NcVVD). The molecular basis of how such diverse results are obtained from the shared phenomenon of blue-light-driven formation of a covalent adduct between FMN and the cysteine side chain remains unclear. One hypothesis suggests that protonation of N5 of the flavin cofactor, changing N5 from a hydrogen bond acceptor to a donor, causes a “flip” of the side chain of a conserved glutamine, with this change in polarity postulated to be communicated through a hydrogen bond donor/acceptor network. The resolution of current crystal structures of lit-state proteins has been too low (≥2.7 Å) to assert the rotamer identity with certainty. Molecular dynamics (MD) simulations offer some support for the N5 protonation/glutamine flip hypothesis, and site-directed mutagenesis of the glutamine residue confirmed its vital importance for the function of distantly related LOV domains, suggesting a common underlying mechanism. While the importance of the conserved glutamine is established, alternative hypotheses of how it governs light
Other recent reports propose that spontaneous thermal reversion re-forms the dark-adapted state. (B) Structure of S-deazaflavin mononucleotide (5dFMN) with a carbon atom (blue) at position 5. (C) Domain topology of Aureochrome1a (Au1a) of Ochromonas danica. Structure of 5-deazaflavin (5dFMN) incorporation on the photochemistry and function of Aureochrome1a (Au1a) of Ochromonas danica.

Aureochromes comprise a family of LOV domain-containing transcription factors found in photosynthetic stramenophiles that regulate the cell cycle and morphophogenesis. Au1a consists of an N-terminal unstructured region, followed by a basic leucine zipper (bZIP) domain and a C-terminal LOV domain. This domain topology is inverted compared to those of most other photoreceptors and means that the A′α helix, instead of the C-terminal Jα helix, connects effector and LOV domains. Spectroscopic and biochemical measurements of the isolated LOV domain from Phaeodactylum tricornutum and Vaucheria frigida Au1a suggest that stepwise unfolding of A′α and Jα helices upon illumination results in LOV domain dimerization. Single-crystal X-ray structures of light-grown LOV domain crystals at 2.7 Å suggested the availability of the core β-sheet for use as a dimerization interface. In dark-state structures, this dimerization site is obscured by the A′α helix. Full-length Au1a has resisted crystallization, but small-angle X-ray scattering (SAXS) of constructs whose unstructured region has been truncated shows significant volume changes that suggest intramolecular bZIP−LOV interactions. Steric caging of the bZIP domain may therefore complement LOV domain-driven dimerization, which is proposed to be the driving force behind Aureochrome DNA binding. Here, we present functional analysis and the first high-resolution crystal structures of a LOV domain with 5dFMN, identifying three conformations for Gln293 of Au1a and the allosteric network linking the chromophore to the A′α helix. This glutamine is widely conserved among LOV domains, and as there are several examples in which truncations of the A′α helix directly influence effectors connected through the Jα helix, these results may have wider implications beyond the Au1a family.

## MATERIALS AND METHODS

### Protein Expression and Purification

Standard molecular biology techniques were employed to generate OdaAu1aLOV and OdaAu1aBZIPLOV constructs from the wild-type O. danica Au1a gene (UniProt, CSNSW6_OCHDN) using oligonucleotides detailed in Table S1. OdaAu1a-derived proteins were obtained by heterologous expression in BL21 (DE3) Escherichia coli in either minimal and autoinduction medium supplemented with glucose [1% (w/v)] and kanamycin (50–100 μg/mL). Cultures were grown at 37 °C until an OD600 of 0.8 was reached, induced with isopentenyl thiogalactoside (0.5 mM, IPTG, Melford), and grown at 25 °C for a further 16 h. OdaAu1a proteins were purified by Ni2+-NTA (5 mL, GE Healthcare) affinity chromatography followed by Resource Q anion exchange (GE Healthcare) chromatography using purification buffer: 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES, 20 mM, pH 7.8), sodium chloride [20 mM (OdaAu1aLOV) or 150 mM (OdaAu1aBZIPLOV)], tris(carboxymethyl) phosphate (TCEP, 0.3 mM), and gradients of imidazole (from 20 to 500 mM) and sodium chloride (from 0 to 1 M). Chromophore exchange was performed by applying the clarified cell lysate to Ni2+-NTA resin (5 mL, GE Healthcare) and washing with 5 column volumes of purification buffer. Proteins were partially unfolded by passing this buffer supplemented with guanidine hydrochloride (6 M) over the resin. To complete FMN elution, a guanidinium thiocyanate...
solution (3 M) was applied until no flavin was observed in the eluent by ultraviolet–visible (UV–vis) spectroscopy. Proteins were refolded by sequentially applying lower concentrations of guanidine hydrochloride (one column volumes of concentrations of 6, 5, 4, 3, 2, and 0 M). The resin was then washed with 5 column volumes of purification buffer, followed by incubation with 1 column volume of purification buffer containing 5dFMN (0.1–0.5 mM) for 30 min. Protein samples were eluted and then further purified as previously described.

**Solution Characterization.** For circular dichroism (CD) experiments, purified protein samples were dialyzed overnight at 4 °C against potassium phosphate buffer (10 mM, pH 7.0). Spectra were collected with an Applied Photophysics Chirascan spectrophotometer. For analytical gel filtration experiments, protein samples were exchanged into gel filtration buffer [HEPES (20 mM, pH 7.4), sodium chloride (100 mM), magnesium chloride (10 mM, and TCEP (0.3 mM)] in centrifugal filter columns. All protein samples were handled in dim red light. For photoactivation, protein samples were illuminated with 450 nm light-emitting diodes (LEDs) until a steady state was reached as determined by UV–vis spectroscopy. For gel filtration experiments, analytical gel filtration columns were either wrapped in aluminum foil for dark experiments or illuminated with 450 nm LEDs for lit-state experiments. For nuclear magnetic resonance (NMR) studies, purified and uniformly 15N-labeled protein samples (400–600 μM) were exchanged into NMR buffer [2-(N-morpholino)-ethanesulfonic acid (MES, 20 mM, pH 6.0), ethylenediamine-nitrateacetate (EDTA, 1 mM), TCEP (1 mM), and sodium azide (0.05%)] and supplemented with 10% deuterium oxide. For dark-state experiments, protein samples were transferred into amber-colored NMR tubes. For lit-state experiments, protein samples were transferred into clear NMR tubes and illuminated with 450 nm LEDs. NMR spectra were recorded on a DPX-600 MHz Bruker NMR spectrometer equipped with a cryoprobe and preamplifiers.

**DNA Binding.** Light-dependent DNA binding was characterized by electrophoretic mobility gel shift assays (EMSAs) using TAMRA-labeled double-stranded DNA containing an OdAu1a recognition site (5'-TGGATGCGTCT-GACGTTGGTTCCAC-3'). EMSA experiments were performed at 4 °C. Dark-state experiments were performed in a room illuminated by dim red light, while for lit-state experiments, protein samples were illuminated for 5 min prior to commencing the experiment and throughout the electrophoresis experiment with 450 nm LEDs. Gels were imaged using a Bio-Rad Chemidoc MP system (Bio-Rad Laboratories) and software provided by the manufacturer.

**Crystallography.** Purified FMN- or 5dFMN-containing OdAu1aLOV was exchanged into crystallization buffer [2-(N-morpholino)ethanesulfonate sodium salt (MES, 50 mM, pH 6.0), sodium chloride (100 mM), magnesium chloride (20 mM), sodium acetate (20 mM), dithiothreitol (DTT, 5 mM), and EDTA (5 mM)] and concentrated to 10–15 mg/mL. Dark-state crystals were grown in plates wrapped with aluminum foil by the hanging drop method. Drops consisted of protein (2 μL, 10 mg/mL) mixed with a reservoir solution [2 μL, 10–20% (w/v) polyethylene glycol (PEG) with an average molecular weight of 2000 or 3000, ammonium chloride (0.1 M), and sodium acetate (0.1 M, pH 4.5–4.9) or disodium citrate, (0.1 M, pH 4.5–4.9)] suspended over further reservoir buffer (100 μL) in 96-well plates (Screw Top Hanging Drop Plate, Molecular Dimensions). Crystal growth was usually evident after 16 h with maximum growth observed after 7 days. For dark-state structures, crystals were cryoprotected with ethylene glycol, harvested, and flash-frozen in liquid nitrogen under dim red light. For illumination experiments, crystals were illuminated with 450 nm LEDs for 30 min, cryoprotected with ethylene glycol, harvested, and flash-frozen in liquid nitrogen. Light-grown crystals were obtained by mixing light-state FMN- or 5dFMN-containing OdAu1aLOV (1.7 μL of a 15 mg/mL solution) with a reservoir solution [2 μL, disodium malonate (1.5–3 M, pH 7.0) and TRIS acetate (0.1 M, pH 7.5–8.0)]. Drops were supplemented with hexaamine cobalt(III) (0.3 μL, 0.1 M). Crystals were grown under blue light and appeared after 1–7 days. Crystals were harvested without cryoprotection and flash-frozen in liquid nitrogen. Data sets were collected from a single crystal each at the Diamond Light Source synchrotron at beamlines I02, 103, and I24. Initial structures were obtained from Phaser 55 or MolRep 55,56 using the dark-state Phacodactylum tricornum Au1aLOV domain (Protein Data Bank entry 5A8B) as a search model. Structures were determined by subjecting initial models to cycles of model building with COOT 57 and refinement using REFMACS. 55 For final R_work and R_free values, see Tables S4 and S5.

**RESULTS**

**OdAu1a with 5dFMN Incorporated Forms a Thermally Stable Cysteinyl-Flavin Adduct.** To investigate the mechanism of LOV domain activation and the effects of introducing 5dFMN (Figure 1B), two truncated versions of *O. danica* Au1a containing the isolated LOV domain (OdAu1aLOV) and the LOV domain with the DNA binding bZIP domain (OdAu1aBZIPLOV) were constructed. The FMN cofactor of the expressed proteins was replaced with 5dFMN by binding the protein to Ni-NTA resin and washing with guanidine thiocyanate followed by removal of the denaturant and incubation with 5dFMN. Refolding of OdAu1aLOV and OdAu1aBZIPLOV in the presence of 5dFMN produced the characteristic blue-shifted vibrational triplet of oxidized 5dFMN with absorbance maxima at 385, 406, and 423 nm (Figure 1E and Figure S1C–F). 41 Comparing the absorbance at 406 and 475 nm indicated that >99% of the cofactor had been refolded. OdAu1aLOV containing FMN reverted from its lit state to its dark state, with a half-life of 112 min, but no reversion was observed for OdAu1aLOV containing 5dFMN even after 7 days (Figure S1C,D). Cycling between lit and dark states using 450 and 330 nm light was possible with no significant photobleaching for at least five cycles (Figure S1E,F). The stability of the 5dFMN adduct was further demonstrated in liquid chromatography–mass spectrometry experiments in which species corresponding to the stable covalent cysteinyl-5dFMN conjugate for OdAu1aLOV were observed but no cysteinyl-FMN conjugates were evident (Figures S2 and S3).

**FMN to 5dFMN Exchange Prevents Light-Induced Dimerization of OdAu1aLOV.** 1H–15N heteronuclear single-quantum coherence NMR spectra of 15N-labeled proteins confirmed that refolding with 5dFMN did not lead to any large-scale structural perturbation. Illumination of OdAu1aLOV bound to 5dFMN resulted in chemical shift perturbations similar to those observed for FMN (Figure S4). CD spectra also indicated that the secondary structure after refolding of 5dFMN-containing OdAu1aLOV was the same as that of native OdAu1aLOV (Figure S5). Both FMN- and 5dFMN-containing
OdAu1aLOV samples exhibited changes in their CD spectra when photoactivated. FMN-containing OdAu1aLOV displayed a 14.2 ± 0.8% decrease in mean residue ellipticity at its 220 nm minimum (Figure 2A and Figure SSC), whereas sDFMN-containing OdAu1aLOV exhibited a smaller change of 8.5 ± 1.0% at 220 nm (Figure 2B and Figure SSD). While UV–vis spectroscopy and mass spectrometry suggested complete and stable adduct formation for sDFMN-containing OdAu1aLOV, the secondary structural changes inferred an intermediate state. Size-exclusion chromatography was used to establish whether sDFMN retained the capacity to induce OdAu1aLOV dimerization in response to light that has been shown for other isolated Aureochromela LOV domains.21,22,49,50 FMN-containing OdAu1aLOV (100 μM) showed clear light-dependent dimerization as determined by size-exclusion chromatography. Dark-state FMN-containing OdAu1aLOV eluted at 13.7 mL with an estimated mass of 20.4 kDa with a slight shoulder toward a larger volume, whereas the lit-state equivalent elution maxima shifted to 12.8 mL in agreement with dimerization (Figure 2C). However, 100 μM sDFMN-containing OdAu1aLOV showed very little shift of the elution volume with peaks at 13.5 and 13.3 mL for the dark and lit states, respectively (Figure 2D). Such an intermediate elution volume most likely represented a monomer–dimer exchange on the time scale of the size-exclusion experiments.

To probe this observation further, we conducted concentration-dependent experiments. The position of the lit-state sDFMN-containing OdAu1aLOV elution peak was strongly concentration-dependent (Figure S6), showing earlier elution at higher concentrations. In an identical concentration range, equivalent FMN-containing samples appeared to elute uniformly at volumes consistent with a dimer [200 to 10 μM (Figure S6)]. Although sDFMN was unable to effect efficient dimerization in OdAu1aLOV, the longer OdAu1aBZIPLOV construct consistently eluted from the size-exclusion column at volumes corresponding to a dimer with both cofactors in the dark and lit states (Figures S7–S9). Strong DNA binding was observed in both states regardless of the cofactor used for 50 μM protein samples. To further probe the light responsiveness of sDFMN, lower concentrations were utilized in DNA binding assays.

Electrophoretic mobility shift assays were used to examine DNA binding by OdAu1aBZIPLOV containing FMN or sDFMN in the dark and under illuminated conditions (Figure 2E–H). Lit-state FMN-containing OdAu1aBZIPLOV uniquely showed a slowly migrating “supershifted” band (Figure 2E),40 while experiments with dark-state FMN (Figure 2F) and both dark and illuminated sDFMN (Figure 2G,H) showed evidence of only a single slower-migrating shifted band. Having demonstrated by size-exclusion chromatography that FMN-containing OdAu1aLOV supports dimerization at 10 μM only when illuminated, the lower band may represent a 1:1 protein–DNA complex while the “supershifted” band most likely corresponds to the functional 2:1 complex of OdAu1aBZIPLOV. The putative 2:1 complex was not observed when sDFMN replaced FMN. Overall, the structural and functional experiments in solution suggest that sDFMN incorporation creates a protein that can form a stable cysteinyl-sDFMN adduct that shows some structural features of a lit-state FMN-containing protein but with incomplete control over the longer-range interactions that direct DNA binding and dimer stability.

sDFMN Forms Cysteinyl-Flavin Adducts at the C4a Position but Induces No Rearrangement of the A’α Helix. To understand how sDFMN can mimic FMN photochemistry but is incapable of complete OdAu1a activation, high-resolution single-crystal X-ray structures for FMN- and sDFMN-containing OdAu1aLOV, were determined for crystals grown in the dark, in the dark and then illuminated with blue light (“illuminated”), and under steady strong blue-light exposure (“light-grown”). The highest-resolution structure of dark-state FMN-containing OdAu1aLOV was obtained at 1.37 Å from a single crystal in space group P2_12_1, with four monomers per asymmetric unit as parallel dimers (Figure 3A).
Crystals in space group $P3_121$ were also observed, but these diffracted poorly. A 1.97 Å structure of dark-state 5dFMN-containing $OdAu1a_{LOV}$ was obtained from crystals grown under identical conditions in space group $P3_121$, indicating a parallel dimer per asymmetric unit (Figure 3D). The identity of the cofactor had little effect on the overall LOV domain structure or the chromophore binding pocket (Figure 4A,D), confirming an identical mode of chromophore binding and no rearrangement of the surrounding environment. When dark-grown crystals were illuminated, the space group changed to $P6_422$ with a single monomer per asymmetric unit (Figure 3B,E). However, once symmetry partners were considered, symmetrical dimers almost identical to the dark-adapted state could be identified with symmetry equivalents. Inspection of the cofactor binding site of the illuminated crystals showed electron density for approximately 30% occupancy of a covalent bond between Cys230 and the cofactor for both FMN and 5dFMN structures (Figure 4B,E). This occupancy that is significantly lower than indicated by UV−vis spectroscopy and MS (Figure 1D,E, and S10) is likely to be the result of a photochemical scission of the covalent adduct during data collection as reported for other LOV domain proteins.29 Although the usual approach under such circumstances is to record multiple data sets from a single crystal, this usually yields much poorer resolution and was therefore not attempted. We hypothesized that higher-resolution data sets could provide unique insights into structural change. To ensure minimal bias in the cycles of structural refinement, we modeled covalent adduct structure at 30% occupancy (cysteinyl-flavin photoadduct) and the dark state at 70% occupancy, yielding two flavin and cysteine orientations. Electron density for a partial occupancy of a cysteinyl-flavin adduct at the C4a position of the isoalloxazine ring for 5dFMN-containing $OdAu1a_{LOV}$ was clearly observed, confirming that 5dFMN forms a photochemical adduct structurally equivalent to the native chromophore.

Figure 3. Dimer arrangements for X-ray crystal structures of FMN- and 5dFMN-containing $OdAu1a_{LOV}$ under dark (left), illuminated (middle), and light-grown (right) conditions. (A) The 1.37 Å structure of dark-state FMN-containing $OdAu1a$. The asymmetric unit contained four monomers as parallel dimers (green) with $A\alpha$ positioned across the $\beta$-sheet surface (half black box). Loops of each monomer lie close to each other (black curved line). (B) The 1.50 Å structure of illuminated crystals of dark-grown FMN-containing $OdAu1a$. The asymmetric unit contained a single monomer (pink), forming a parallel dimer similar to that in the dark state when considering a symmetry equivalent (gray). (C) The 1.66 Å structure of light-grown FMN-containing $OdAu1a$ featuring a unique dimer arrangement with $A\alpha$ being repositioned across a $\beta$-sheet surface (black box) and loop region rearrangement (dashed arrow). (D) The 1.97 Å structure of dark-state 5dFMN-containing $OdAu1a$ with a dimer similar to dark-state FMN. (E) The 1.43 Å structure of illuminated 5dFMN-containing $OdAu1a$ with a symmetry partner equivalent to a dimer colored gray. (F) The 2.00 Å structure of light-grown 5dFMN-containing $OdAu1a$ showing a similar loop (black curved line) and $A\alpha$ helix arrangement (black box) as for dark-state and illuminated proteins with a symmetry equivalent colored gray.

Figure 4. Electron density maps (gray mesh) for FMN or 5dFMN, Cys230, and residues forming hydrogen bonding networks among O4 of FMN, Asn272, Gln293, and Asn194 are displayed at the $\sigma = 1$ level. Partial occupancies are colored by characteristic conformations observed for dark-state (green), illuminated (orange), or light-grown (purple) structures. Yellow dashed lines indicate predicted hydrogen bonding. (A) Dark-state FMN (1.36 Å). (B) Illuminated FMN (1.50 Å). (C) Light-grown FMN (1.67 Å). (D) Dark-state 5dFMN (1.97 Å). (E) Illuminated 5dFMN (1.43 Å). (F) Light-grown 5dFMN (2.00 Å).
Light-grown crystals could not be obtained under the conditions used for the dark state, but alternative conditions produced monochinic crystals in space group C121 for the FMN sample and hexagonal crystals in space group P6_{1}2_{2} for 5dFMN. For light-grown FMN-containing OdAu1a\textsubscript{LOV}, no cysteinyl-FMN adduct was evident in the electron density map. Electron density corresponding to a cysteinyl-5dFMN adduct was observed but was less prominent than in maps from illuminated crystals. Notably, light-grown FMN-containing OdAu1a\textsubscript{LOV} contained four monomers per asymmetric unit as parallel dimers. Two of the monomers appeared to be identical to the dark-state structure, while the second pair showed a different A′α (Figure 3A,C). In dark-state structures, a change in the relative positions of strand \(β^′\) (287–293) of the β-sheet and A′α (183–189) of 12° is observed. This rearrangement does not occur in illuminated structures, probably due to crystal lattice constraints. Light-grown 5dFMN-containing OdAu1a\textsubscript{LOV} maintained a single monomer per asymmetric unit, resembling the arrangement of illuminated structures. This supported solution data that although 5dFMN undergoes photochemistry similar to that of FMN, it is unable to fully activate OdAu1a\textsubscript{LOV}. Taken together, this suggests that the A′α rearrangement, observed for only light-grown FMN-containing OdAu1a\textsubscript{LOV}, could correlate with dimerization in solution (Figure 3A,C).

Adduct Formation Populates Different Conformations of Gln293. Dark-state structures gave single well-defined populations of Gln293, Asn272, and Asn194 for both FMN and 5dFMN, but close examination of electron density maps from illuminated and light-grown conditions yielded multiple conformations for these residues (Figure 4). In dark-state structures, Gln293 lies close to the chromophore and forms a probable hydrogen bond to the O4 position (Figure 4A,D). For illuminated structures, a 20% occupancy of a new conformation of Gln293, with its side chain away from the FMN binding pocket, was evident (Figure S22). Additional conformations of Asn194 and Asn272 are also observed. Formation of a new hydrogen bond network among these three residues creates a route for the conformation of Gln293 to be reoriented to the A′α helix through Asn194 (Figure 4B,E), which is located in the loop connecting A′α with the LOV domain core. Examination of the FMN binding pocket of the light-grown crystal structure revealed a third arrangement for Gln293 and Asn194. In the parallel dimer with a unique A′α arrangement, Asn194 moves in toward Gln293. This coincides with a probable change in the orientation of the Gln293 side chain and the polarity of the hydrogen bond network due to flavin protonation (Figure 4C). In contrast, 5dFMN-containing OdAu1a\textsubscript{LOV} did not form this “flip” conformation but closely resembled the structure of illuminated 5dFMN-containing OdAu1a\textsubscript{LOV} with identical Asn194 and Gln293 conformations (Figure 4F). This suggests that the structural changes that we observed were not an artifact of different crystallization conditions, as identical space groups were achieved for 5dFMN under both conditions. It appears that only growing crystals of FMN-containing protein under constant illumination allow the structural reorientation of the allosteric A′α helix to support dimer rearrangement (Figure 3).

DISCUSSION

Reconstitution of truncated versions of the light-dependent transcription factor OdAu1a\textsubscript{LOV} with 5dFMN led to proteins that undergo photoadduct formation to produce a thermally stable cysteinyl-5dFMN adduct. Despite clear evidence of adduct formation captured by UV spectroscopy and mass spectrometry and subsequent light-induced changes determined by CD and NMR spectroscopy, 5dFMN-containing OdAu1a\textsubscript{LOV} does not dimerize under the conditions where dimerization of FMN OdAu1a\textsubscript{LOV} occurs. High-resolution crystal structures show identical FMN and 5dFMN binding modes in dark-grown crystals, suggestive of identical chromophore binding characteristics. Crystal structures of illuminated and light-grown OdAu1a\textsubscript{LOV} containing 5dFMN provide conclusive evidence of cysteinyl photoadduct formation at the C4a position in apparent support of the radical-based mechanism proposed for the native chromophore.31

Crystal structures obtained under different illumination conditions define three distinct conformations for conserved Gln293 and its hydrogen bonding partners. For the FMN-containing light-grown crystal structure, inspection of calculated difference maps with both rotamers strongly implies a glutamine “flip” (Figure S22). Protonation of FMN and a corresponding “flip” of the glutamine side chain is a leading hypothesis for LOV activation9,32,33 and has even been used to explain the activation of a LOV domain containing a neutral semiquinone flavin.31 However, in our and other published light-grown structures,9,32 the distance between Gln293 and N5 of FMN is longer than might be expected for a hydrogen bond (~3.3 Å). 5dFMN forms the equivalent covalent adduct, but in contrast to FMN, Gln293 does not appear to “flip” in
light-grown crystals (Figure 4C,F). Taken with 5dFMN’s inability to induce light-dependent dimerization, this furthermore suggests that N5 protonation is a prerequisite for locking the liganditation state of OdAu1aLOV. Comparison of illuminated and light-grown FMN-containing OdAu1aLOV structures (Figure 4B,C) suggests that a key aspect of the Gln293 “flip” is to engage an alternative conformation of the side chain of Asn194, located between the Aβ strand and Aα helix, in hydrogen bonding. This change in the Asn194 conformation may be the key to propagating the effects of adduct formation beyond the LOV domain, by rearranging the domain to favor dimerization and/or by releasing the Aα helix. Notably, this key Asn residue is also found in other Au1a homologues24,49,50 and in AsloV2.51

To the best of our knowledge, our structures of illuminated crystals of 5dFMN-containing OdAu1aLOV provide the first experimental evidence for a further arrangement of Gln293 and Asn194. For both FMN and 5dFMN, Gln293 “swings” away from the chromophore when illuminated (Figure 5). The persistence of a “swing” conformation in 5dFMN light-grown crystals suggests that it is not a crystallographic artifact generated by illuminating LOV domains trapped in the crystal lattice or a product of a different space group due to changes in crystallographic conditions but that 5dFMN is unable to support progress to the “flip” state. CD measurements indicate that illumination of 5dFMN-containing OdAu1aLOV results in some secondary structural changes, although not to the extent seen with FMN. Likewise, size-exclusion chromatography revealed intermediate changes upon illumination for 5dFMN. These results infer the “swing” conformation of Gln293, formed in the absence of larger-scale secondary structural changes, provides a degree of activation. It therefore seems probable that the “swing” state represents an intermediate stage in activation rather than an unproductive conformation (Figure 5).

The key determinants of success for LOV domain-based optogenetic systems are the dynamic ranges of affinities and activities in the dark and lit states. Most previous work has relied on using molecular modeling to guide alterations to helix docking propensities to improve the dynamic range of optogenetic tools. Here we provide experimental insight into the molecular basis of LOV domain photoactivation. The nature of the “swing” state may be crucial for improving LOV domains by rational design; if the “swing” state is an on-path intermediate, then encouraging its formation is of key importance, placing a greater emphasis on the O4—Gln293—Asn194 axis for initial activation. This is in agreement with MD simulations and Fourier transform infrared spectroscopy experiments that identified hydrogen bond changes to O4 of the FMN ring being important for the regulation of LOV domain activation especially in the early stages after photoadduct formation.25,47,59,60 Indeed, results that inferred a role for N5 protonation by generation of a neutral flavin semiquinone radical25,51 and N5-protonated reduced flavins,53 also predict significant polarity changes at O4.37 Alternatively, if the “swing” state is an off-path intermediate, its destabilization may lead to improved switches with higher dynamic ranges. Understanding these fundamental aspects of domain activation has a potentially enormous impact for the design of new tools based on LOV domains and may allow researchers to improve the performance of designed LOV domains with multiple optogenetic applications.

### Supporting Information

The Supporting Information is available free of charge on the ACS Publications website at DOI: 10.1021/acs.biochem.9b00255.

Experimental procedures, including purification, characterization, and crystallization methods; UV–vis spectroscopy, mass spectrometry, NMR, CD, and SEC data of OdAu1a (Figures S1–S10, S22) and 5-deazaflavin mononucleotide chemoenzymatic synthesis (Figures S11–S21); and tables of DNA oligonucleotides, protein sequences, and structural refinement statistics (Tables S4 and S5) (PDF)

### Accession Codes

Protein Data Bank entries 6I20, 6I21, 6I22, 6I23, 6I24, and 6I25.

## AUTHOR INFORMATION

### Corresponding Author

*E-mail: allemannrk@cardiff.ac.uk.

### ORCID

Mindaugas E. Kalvaitis: 0000-0002-8175-7552

### Funding

This work was supported by BBSRC Grants BB/M006158/1 and BB/P009980/1 and EPSRC Grant EP/L027240/1.

### Notes

The authors declare no competing financial interest.

## ACKNOWLEDGMENTS

The authors thank Dr. Harald Janovjak (IST Austria) for providing the DNA encoding full-length O. danica Aureochrome1a, Dr. Yi Jin for help with structure determination and helpful discussions, and Tom Williams for assistance with mass spectrometry. The authors thank the Diamond Light Source for beamtime (Proposal mx14843) and the staff of beamlines 102, I03, and I24 for assistance with data collection.

## ABBREVIATIONS

OdAu1a, O. danica Aureochrome1a; LOV, light-oxygen-voltage; bZIP, basic leucine zipper; FMN, flavin mononucleotide; PAS, Per-ARNT-Sim; 5dFMN, 5-deazaflavin mononucleotide; CD, circular dichroism; SAXS, small-angle X-ray scattering; MD, molecular dynamics; NMR, nuclear magnetic resonance.
