Lattice QCD (LQCD) studies for the hadron vacuum polarization (HVP) and its contribution to the muon anomalous magnetic moment ($g - 2$) are reviewed. There currently exists more than 3-$\sigma$ deviations in the muon $g - 2$ between the BNL experiment with 0.5 ppm precision and the Standard Model (SM) predictions, where the latter relies on the QCD dispersion relation for the HVP. The LQCD provides an independent crosscheck of the dispersive approaches and important indications for assessing the SM prediction with measurements at ongoing/forthcoming experiments at Fermilab/J-PARC (0.14/0.1 ppm precision). The LQCD has made significant progresses, in particular, in the long distance and finite volume control, continuum extrapolations, and QED and strong isospin breaking (SIB) corrections. In the recently published papers, two LQCD estimates for the HVP muon $g - 2$ are consistent with *No New Physics* while the other three are not. The tension solely originates to the light-quark connected contributions and indicates some under-estimated systematics in the large distance control. The strange (s) and charm connected as well as uds-disconnected contributions are consistent among all LQCD groups and determined precisely enough with respect to the target precision ($\mathcal{O}(0.1\%)$). The total error is at a few percent level. It is still premature by the LQCD to confirm or infirm the deviation between the experiments and the SM predictions. If the LQCD is combined with the dispersive method, the HVP muon $g - 2$ is predicted with 0.4% uncertainty, which is close upon the target precision required by the Fermilab/J-PARC experiments. Continuous and considerable improvements are work in progress, and it is quite probable that the LQCD will provide the HVP muon $g - 2$ with the required precision within a few years.
1. Introduction

Since the discovery of the Lamb shift, the anomalous magnetic moment of charged leptons ($a_{\ell} = (g_{\ell} - 2)/2$, $g_{\ell}$ = gyro-magnetic factor) have accompanied the development of quantum field theory (QFT). For electrons ($a_{e} = e/(2m_e)$), it is one of the most precisely measured and computed quantities in science with a total uncertainty below 1 ppb. Theory and experiment agree, which is a great success of the QFT and the standard model of particle physics (SM). The gyro-magnetic factor $g_{\ell}$ relates the lepton spin to its magnetic moment: $\hat{M} = g_{\ell}(e_{el}/(2m_{\ell}))\vec{s}$ where $e_{el}$ and $m_{\ell}$ denote the electric charge and lepton mass, respectively. A finite $a_{\ell}$ shows a deviation from $g_{\ell} = 2$ predicted by the Dirac theory and accounts for quantum loop (QFT) corrections with particles in the SM and possibly physics beyond the standard model (BSM). With respect to the BSM search, the muon anomalous magnetic moment ($a_{\mu} = e/(2m_{\mu})$) is under active scrutiny both theoretically and experimentally; there currently exists tension of more than 3-$\sigma$ deviations between the experiment with 0.5 ppm precision [3] and the SM prediction (quoted from [4], see also [5, 6]):

$$10^{10} a_{\mu}^{exp.} = 11659208.9 \pm 6.3 \text{ (0.54ppm)}, \quad 10^{10} a_{\mu}^{SM} = 11659184.0 \pm 5.9 \text{ (0.51ppm)},$$ (1.1)

In fact, $a_{\mu}$ is generically much more sensitive to the massive BSM particles than $a_{e}$ since the BSM contributions are proportional to the lepton mass squared, i.e. 40000 times larger for the muon.

In the theory side, the largest source of uncertainty (over 79%) in the total error of $a_{\mu}^{SM}$ comes from the non-perturbative estimate of the leading-order (LO) hadron vacuum polarization (HVP), $\hat{\Pi}(Q^2)$ contributions to the anomaly ($a_{\mu}^{LO-HVP}$, Fig. 1). In Eq. (1.1), the $a_{\mu}^{LO-HVP}$ in the SM prediction utilizes the second-subtracted QCD dispersion relation for the HVP,

$$\hat{\Pi}(Q^2) = \int_0^\infty ds \frac{Q^2}{s(s+Q^2)} \operatorname{Im} \Pi(s) = \int_0^\infty ds \frac{Q^2}{s(s+Q^2)} \frac{-R(s)}{12\pi^2}. \quad (1.2)$$

The HVP imaginary part $\operatorname{Im} \Pi(s)$ describes hadron decay resonances and the second equality is the optical theorem $\operatorname{Im} \Pi(s) = -R(s)/(12\pi)$ with $R(s) = \sigma[s; e^+ e^- \to \text{hadrons}]/(4\pi \alpha(s)^2/(3s))$, where $\alpha = e^2_{\text{el}}/(4\pi)$. This dispersive method provides the most precise prediction of $a_{\mu}^{LO-HVP}$ today. However, the systematics hidden in $R(s)$ is challenging to be controlled in its integral to get $\hat{\Pi}$ and $a_{\mu}^{LO-HVP}$. In fact, there exists some tension in the input data of $\sigma[e^+ e^- \to \pi^+ \pi^-]$ [7].

Lattice QCD (LQCD) which does not rely on any experimental inputs can provide an independent cross-check of the dispersive approach. Since the pioneering work [8], the LQCD has made significant progress [1]. The LQCD precision will become competitive to the dispersive method in the coming years. The ultimate goal of the LQCD is to provide the $a_{\mu}^{LO-HVP}$ in $\mathcal{O}(0.1)\%$ precision which is required with respect to the ongoing/forthcoming experiments; 1) in Fermilab (FNAL-E989), a new measurement of $a_{\mu}$ aiming at 0.14 ppm uncertainty has been started [9], 2) in J-PARC-E34, an experiment with a new technology using an ultra-cold muon beam is planned [10].
and aims at 0.1 ppm precision with completely different systematics from both BNL and Fermilab. In addition, the MUonE (CERN) project [11] plans to measure the QED running coupling constant \(\alpha(s)\) precisely and provides the HVP with spacelike low momenta, which can be combined with the HVP by the LQCD and allow the precise estimate of the \(a_{\mu}^{LQCD}\) [12]. Moreover, the LQCD HVP is applied to the precision science of the weak running coupling constant at low momenta [13], which is another place to assess the SM with experimental data (e.g. PLISMA-Mainz [14]).

This proceedings reviews LQCD results for the HVP \(\hat{\Pi}(Q^2)\) and its contribution to the anomaly \(a_{\mu}^{LQCD}\) (in particular, muon case \(\ell = \mu\)). Comparing to the recent comprehensive review [1], we concentrate on the LO-HVP contribution to the anomaly and include updated results in addition to the published ones. In the next section, we explain formulas for the \(\hat{\Pi}(Q^2)\) and \(a_{\mu}^{LO-HVP}\). In Sec. 3, we review the progresses on the long distance and finite volume control, continuum extrapolations, and SIB/QED corrections. Then, we compare the \(a_{\mu}^{LO-HVP}\) and related quantities obtained in various LQCD groups and discuss a combined analysis of LQCD and dispersive method in Sec. 4. Finally, Sec. 5 gives concluding remarks and the outlook for further improvements in the LQCD estimates of \(a_{\mu}^{LO-HVP}\). The appendix shows summary tables for the published and updated results of \(a_{\mu}^{LO-HVP}\) and related quantities.

2. Methodology

Consider a scattering process of a charged lepton (\(\ell^-\)) from a photon (\(A_{\mu}\)). The amplitude is expressed as

\[
\mathcal{M}(p, p')/(2\pi)^4 \delta^{(4)}_{p, p'} = -ie_q u_{\ell}(p')\Gamma_{\nu}(p', p)u_{\ell}(p)A_{\nu}(p - p') ,
\]

where \(u_{\ell}\) represents a Dirac spinor of the lepton, \((p - m_\ell)u_{\ell}(p) = 0\), and \(\Gamma_{\nu}\) denotes an electromagnetic vertex operator. Figure 1 is an example for the vertex function with HVP. In QCD/QED, which preserves the \(CP\) symmetry, \(\Gamma_{\mu}\) consists of only electric and magnetic terms, \(\Gamma_{\mu}(p', p) = F_1^\ell(q^2)\gamma^\mu + F_2^\ell(q^2)(i\sigma_{\mu\nu} q_\nu/(2m_\ell))\), where \(\gamma^\mu = (p' - p)^\mu\) and \(F_1^\ell, F_2^\ell\) is known as the Dirac (Pauli) form factor. The anomaly is then obtained from the form factor [15]:

\[
a_{\ell}(s) = (g_{\ell} - 2)/2 = F_1^\ell(0) \quad (\text{c.f.} F_1^\ell(0) = 1 \text{ in all order}).
\]

At tree level, \(\Gamma_{\mu} = \gamma^\mu\) and \(a_{\ell} = 0\). At one-loop, the vertex function \(\Gamma_{\mu}\) is the one without HVP blob in Fig. 1, giving the famous Schwinger’s result:

\[
a_{\ell}(s) = (\alpha_s/\pi) \int_0^s d\hat{\bar{s}}\ K(\hat{s}) = \alpha_s/(2\pi) \quad \text{with} \quad \alpha = e_c^2/(4\pi).
\]

2.1 Target Quantity

Our target is the leading-order (LO, \(\sim \mathcal{O}(\alpha_s^2)\)) HVP contribution to the charged lepton (in particular, muon) \(g - 2\) shown in Fig. 1, and obtained by inserting a photon-irreducible HVP function (\(\hat{\Pi}\)) into the one-loop expression,

\[
a_{\ell}^{LO-HVP} = \left(\frac{\alpha_s}{\pi}\right)^2 \int_0^\infty dq^2 \frac{K(\hat{s})}{m_\ell^2} \hat{\Pi}(q^2), \quad \hat{\Pi}(Q^2) = 4\pi(\Pi(Q^2) - \Pi(0)),
\]

\[
K(\hat{s}) = \frac{\hat{s}(Z(\hat{s}))^2}{1 + \hat{s}(Z(\hat{s}))}, \quad Z(\hat{s}) = \frac{\hat{s} - \sqrt{\hat{s}^2 - 4\hat{s}}}{2\hat{s}}, \quad \hat{s} = \frac{Q^2}{m_\ell^2}.
\]

\(^2\text{In the one-loop calculation, the lepton mass } m_\ell \text{ is absorbed into the integral variable } \hat{s} = Q^2/m_\ell^2 \text{ and the Schwinger’s result holds for arbitrary charged leptons: } e/\mu/\tau.\)
where $\Pi(Q^2)$ is the scalar part in the electromagnetic vector current ($j_\mu$) correlator with up, down, strange, and charm quarks ($\psi_{f=u,d,s,c}(x)$),

$$\Pi_{\mu\nu}(Q) = (\delta_{\mu\nu}Q^2 - Q_\mu Q_\nu)\Pi(Q^2) = \int d^4x \, e^{iQx}G_{\mu\nu}(x)\,, \quad G_{\mu\nu}(x) = \langle \text{Re}[j_\mu(x)j_\nu(0)] \rangle \,, \quad (2.3)$$

$$j_\mu(x) = \sum_{f=u,d,s,c} q_f j_\mu^f(x) = \sum_f q_f (\bar{\psi}_f \gamma_\mu \psi_f)(x)\,, \quad (\psi_{u,c},q_{d,s}) = (2/3,-1/3)\,.$$

In the muon case $\alpha^{\text{LO-HVP}}_{e=\mu}$, the required precision is $\mathcal{O}(0.1\%)$ which amounts to 0.1 ppm (target precision of the experiments [9, 10]) in the total $a_\mu$. The bottom- and top-quark effects are negligible for that precision (the bottom quark contribution is estimated to be below 0.05% in $a_\mu^{\text{LO-HVP}}$ [16]). In contrast to the one-loop expression mentioned above, the integrand in Eq. (2.1) is not a function of the single variable $\vec{x}$; the lepton mass $m_\ell$ sets a typical scale via $K(\langle \hat{\delta} \rangle)/m_\tau^2$ and the integrand has a peak around $Q^2 = (m_\ell/2)^2$. Once the HVP $\hat{\Pi}(Q^2)$ is calculated, $a_\ell$ could be evaluated for arbitrary leptons, $\ell = e/\mu/\tau$, as long as systematics in $\hat{\Pi}(Q^2)$ near $Q^2 = (m_\ell/2)^2$ are controlled.

We shall define the LO-HVP contribution $\alpha^{\text{LO-HVP}}_{e=\mu}$ more precisely; (1) as shown in Fig. 1, only two internal photons connected with the HVP blob attach the external lepton lines, and (2) only one HVP blob which is irreducible with respect to a photon line cutting is inserted. Two photons in (1) give rise to $\mathcal{O}(\alpha^2)$ - the prefactor in Eq. (2.1). The condition (2) excludes most of diagrams with additional $\alpha$ but still allows photons and fermion-loops inside the single-irreducible HVP blob $\hat{\Pi}$. We shall call them as QED corrections in LO-HVP. From now on, our target quantity $\alpha^{\text{LO-HVP}}_{e=\mu}$ is considered to include such QED corrections $\mathcal{O}(\alpha^{eff})$ in addition to the pure-QCD effects $\mathcal{O}(\alpha^2)$. For the target precision, the leading QED correction must be considered: $\mathcal{O}(\alpha^3)/\mathcal{O}(\alpha^2) \sim \alpha \sim 1\% > 0.1\%$. In comparing/combining the LQCD to the dispersive method (1.2), the QED corrections must be taken account in the LO-HVP side since it is impossible to extract the pure QCD HVP alone in the dispersive method. The other $\mathcal{O}(\alpha^3)$ diagrams, with three internal photons attaching the leptons, two HVP blobs, or one HVP blob and one lepton loop independent of the HVP blob are considered as next-to-leading-order (NLO) contributions, which is investigated in Ref. [17] and not studied in this proceedings.

The simulation output in LQCD is the correlator $G_{\mu\nu}$ in Eq. (2.3), which is composed of the connected and disconnected correlators,

$$G(t) = (1/3) \sum_{i=1}^3 \sum_{\bar{x}} G_{ii}(\bar{x},t) = (\sum_f C_f^i + D)(t)\,, \quad (2.5)$$

$$C_f^i(t) = -(a_3^i/3) \sum_{i=1}^3 q_f^2 \sum_{\bar{x}} \langle \text{ReTr}[\gamma S_f^i(x,0)\gamma S_f^i(x,0)] \rangle \,, \quad (2.6)$$

$$D(t) = (a_3^i/3) \sum_{i=1}^3 q_f q_f^i \sum_{\bar{x}} \langle \text{Re\{Tr}[\gamma S_f^i(x,x)\gamma S_f^i(y,y)]\} \rangle |_{y=0} \,.$$

$S_f^i(x,y)$ is a quark propagator ($\{ \mathcal{D}_f(x,y) \}^{-1}$) with flavor $f$ and estimated by solving the stochastic Dirac equation $\mathcal{D}_f(y,z)\phi^{(r)}(z) = \eta^{(r)}(y)$ where $r \in [1,N_r]$ and $\eta^{(r)}(y)$ is a stochastic noise vector satisfying the condition: $\lim_{N_r \to \infty} N_r^{-1} \sum_{r=1}^{N_r} \eta^{(r)}(x)\eta^{(r)}(y) = \delta_{xy}$. For $C_f^{\text{nd}}(t)$ and $D(t)$, the measurements are usually carried out with $\mathcal{O}(10^3)$ or more stochastic sources together with all-mode-averaging (AMA) technique (low-lying eigen-mode averaging over all lattice points +
precise-sloppy measurements with stochastic sources). In particular for $D(t)$, one needs the estimate of so-called loop contributions $t'_n(t) = a^3 \sum \text{Tr}[\gamma_\mu S^I(x,x)]$ and the stochastic estimate $t'_n(t) = a^3 \sum \sum_i \text{Tr}[\rho_i \phi^{(i)}(x)]$ greatly decreases the computational cost [18, 19, 20, 21, 22]. In the isospin limit, the up, down, and strange contributions to the disconnected part is simplified as $D(t) = \langle Q_\mu \rangle \equiv (\omega, Q_{i=1,2,3}) = (\omega, 0)$ in Eq. (2.3) which leads to $\Pi(\omega^2) = \sum_i \Pi_i(\omega)/3(\omega^2)$. We work in the continuous spacetime and shows in later the formulas applies to the lattice system.

We shall derive formulae [23] relating the LQCD output $G(t)$ to our target quantities, $a^3 \Pi^0_{HVP}$ and $\hat{\Pi}$. In the continuous spacetime and shows in later the formulas applies to the lattice system. First, we use the property of $\Pi_{\mu\nu}(\omega \to 0) = \int d^4x G_{\mu\nu}(x) = \int d^4x \partial_\mu (x_\nu G_{\nu\nu}(x)) = 0$, where the second equality results from the vector current conservation $\partial_\mu j_\mu(x) = 0$. Second, specify the momentum as $(Q_\mu) = (\omega, Q_{i=1,2,3}) = (\omega, 0)$ in Eq. (2.3). And finally, note the fact that $\Pi(\omega^2)$ is even function of $\omega$. From these properties, the Fourier transformation in Eq. (2.3) reduces into $\Pi(\omega) = \int d\omega (\cos[\omega t] - 1) G(t)/\omega^2$. Using $\Pi(\omega \to 0) = -\int dt(t^2/2)G(t)$, we obtain [23]

$$\hat{\Pi}(\omega^2) = \int_0^\infty dt \, t^2 \left(1 - \sin^2 [\omega t / 2]\right) G(t),$$

(2.8)

where $\sin[x] = x^{-1} \sin x$, and

$$a^3 \Pi^0_{HVP} = \left(\frac{\alpha}{\pi}\right)^2 \int_0^\infty dt \, W(t, \omega^2/m_f^2) G(t), \quad W(t, \omega^2/m_f^2) = \int_0^\infty d\omega^2 \frac{K(\omega^2/m_f^2)}{m_f^2} \, t^2 \left(1 - \sin^2 \left[\frac{\omega t}{2}\right]\right).$$

(2.9)

The integrands in Eqs. (2.8) and (2.9) are regular at $t \to 0$, $t \to \infty$, $\omega \to 0$, and/or $\omega \to \infty$.

The above equations are the expressions in the continuum and infinite volume limits. In LQCD with a finite volume ($FV$, $L^3 \times T$) and lattice spacing ($a$), the Ward-Takahashi Identity (WTI) for lattice symmetries ($\sum_\mu \hat{Q}_\mu \Pi_{\mu\nu}(Q) = 0$ with $\hat{Q}_\mu = (2/a) \sin[(a/2)(2\pi n/L)]$) does not exclude longitudinal components of $\Pi_{\mu\nu}$, a part of which becomes a large FV effect at infra-red limit. Replacing $\Pi_{\mu\nu}(Q^2)$ with $\Pi_{\mu\nu}(Q^2) = \Pi_{\mu\nu}(Q^2) - \Pi_{\mu\nu}(0)$ in Eq. (2.3), the derivation of Eqs. (2.8) and (2.9) can be repeated in the LQCD case.

We shall consider the Taylor expansion of the HVP: $\hat{\Pi}(\omega^2) = \sum_{n=1}^\infty \Pi_n(\omega^2)$. Using Eq. (2.8) in the LQCD case ($t = ia, \ell \in \mathbb{Z}$), the coefficients $\Pi_n$ are evaluated from the LQCD output $G(t)$,

$$\Pi_n = \frac{1}{n!} \frac{d^n \hat{\Pi}}{d\omega^{2n}} \bigg|_{\omega \to 0} = \sum_{\ell=0}^{n+1} \frac{(-t^2)^n}{(2n+2)!} \Pi_n(\omega^2) G(t).$$

(2.10)

The integrand in the right hand side has a peak, which is shifted to the larger $t$ direction with increasing $n$ because of the factor $(t^2)^{n+1}$. Therefore, one finds $\Pi_n(\omega \to 0) \neq 0$ unlikely to the vector case. As a result, the Fourier transformation reduces into the cosine term without $"-1"$.

3If one investigates the HVP with an axial vector current ($j_\mu^{axial}$), the current conservation does not hold due to the chiral symmetry breaking: $\partial_\mu j_\mu^{axial}(x) = (m_u + m_d)G^{axial}(x)$. Therefore, one finds $\Pi_n(0) \neq 0$ unlikely to the vector case. As a result, the Fourier transformation reduces into the cosine term alone without $"-1"$.

4Besides FV effects, the WTI with a finite lattice spacing allows a term proportional to the derivative of the scalar HVP, $d^3 \Pi / dQ^2$, in Eq. (2.3). However, they have dimension $(-2n)$ and vanishes at least quadratically ($n \geq 1$) in the continuum limit. In considering $a^3 \Pi^0_{HVP}$, the HVP with low momenta dominantly contributes, and the derivative terms would be negligible [24].

4
the peak, and allows a scale-by-scale comparison of LQCD results from different groups (Sec. 4.1). Moreover, the slope $\Pi_I$ is an important LQCD input for the combined estimate of the $a_\mu^{LO-HVP}$ with the LQCD, experimental data, and QCD sum rule [25]. As shown in the followings, $\Pi_n$ provides a key ingredient in several approximants in the IR region.

### 2.2 Approximants

In the muon case, the typical scale $Q^2 = (m_\mu/2)^2$ in the integral (2.1) is less than half of a pion mass squared ($m_\pi^2$). In LQCD with finite volume ($L^3 \times T$), it is hopeless to get enough data points around that momentum region (c.f. $L m_\pi \lesssim 4 - 6$). One needs some approximants for $\hat{\Pi}(Q^2 \sim (m_\mu/2)^2)$. To minimize associated systematics, the model independent approximants (e.g. unlikely to the vector-meson dominance) are preferable and reviewed in the followings.

#### Time-Momentum Representation [23]

In the LQCD estimate of $a_\mu^{LO-HVP}$, introducing the strict lattice momenta is not mandatory: in Eq. (2.8), replace the continuous $t$ with the lattice one $i a$ ($i \in \mathbb{Z}$) but keep continuous-valued $\omega$, $\hat{\Pi}^{TMR}(\omega^2) = a^3 \sum_{i=1}^{N_T} t_i^2 (1 - \sin^2 |\omega a/2|) G(i)$, which is called the time-momentum representation (TMR) [23], and one of the popular choices today. The approximants converges to the correct continuum limit. Example of the integrand in Eq. (2.1) with $\hat{\Pi}^{TMR}(\omega^2)$ is shown in Fig. 2. In LQCD, we need an IR-cut in $\sum_t$ and a UV-cut $\omega_{cut} \lesssim \pi/(2a)$ in the integral in Eq. (2.9) to control the associated systematics (see, for example, the supplemental material of Ref. [21]).

#### Padé Approximants [26]

To investigate the deep IR region, $Q^2 = (m_\mu/2)^2$, it is natural to utilize the zero-momentum Taylor coefficients (2.10). We shall consider the $[M,N]$ Padé approximants, $\hat{\Pi}(Q^2;M,N) = (\sum_{m=1}^M A_m Q^{2m})/(1 + \sum_{n=1}^N B_n Q^{2n})$ ($A_0$ term should be zero: $\hat{\Pi}(0) = 0$ by definition (2.1)). The coefficients $(A_m, B_n)$ are then constructed from the Taylor coefficients $\Pi_t$ (2.10) (the generalization $\omega^2 \to Q^2$ is trivial). Consider the first two approximants: $\hat{\Pi}(Q^2;2,1,0) = Q^2 \Pi_I$ and $\hat{\Pi}(Q^2;1,1) = \Pi_I Q^2/(1 - Q^2 / \Pi_I)$. If the $\hat{\Pi}(Q^2;1,0)$ is adopted for whole $Q^2 = \omega^2$ in Eq. (2.1), the integral gives an upper bound on the true value of the $a_\mu^{LO-HVP}$ (either $a_\mu^{LO-HVP}$). Else if the $\hat{\Pi}(Q^2;1,1)$ is adopted, the integral (2.1) accounts for more than 98% of the integral with full $\hat{\Pi}(Q^2)$. The HVP $\hat{\Pi}(Q^2)$ satisfies the dispersion relation (1.2), which is seen as the Stieltjes integral [26] due to the positivity of the integrand $\text{Im}\Pi$. This property guarantees that the $\hat{\Pi}(Q^2)$ is approximated by the Padé approximants with a finite convergence radius. Usually, $[2,1]$ or $[1,1]$ Padé approximants is used in the hybrid method; use the Padé approximants for IR region ($Q^2 < Q^2_{IR} \sim 0.2$ GeV$^2$) in Eq. (2.3), adopt the trapezoid (or similar) integral for intermediate momenta $Q^2 \in [Q^2_{IR}, Q^2_{UV}]$ with $Q^2_{UV} \sim 4$ GeV$^2$, and evaluate higher momentum contributions with perturbative QCD. The systematics is estimated by varying the cuts $Q^2_{IR/UV}$. One could also use the approximants for whole $Q^2$ region by assuming that the true integral exists in between the in-
tetrals obtained with \([N,N]\)- and \([N,N−1]\)-th approximants, whose difference is used to estimate the systematic error [16].

Others Two other approximants - the Mellin-Barnes (MB) approximants and the Lorentz-covariant coordinate-space (CCS) representation - have been proposed. The MB approximants are based on the fact that the spectrum \(\text{Im} \Pi(s)/\pi\) in QCD is positive and approaches a constant as \(s \rightarrow \infty\), and thereby, reproduce the relevant asymptotic behavior at large \(s\) in contrast to some classes of Padé approximants (e.g. \([N,N−1]\]-Padé). See, Ref. [27] for details. The MB approximants can be constructed by using the moments (2.10) calculated by the LQCD for which one must confirm that the convergence condition (Sec. III.B in Ref. [27]) is satisfied. The MB has been adopted in the phenomenological estimate of \(a^\text{LO-HVP}_{\mu}\) [28]. In LQCD, the MB is calculated in Ref. [29] and utilized to evaluate the NLO \(\mathcal{O}(\alpha^3)\) HVP contributions [17]. Another approximants, the CCS representation, introduces the IR-cut in the radial coordinate for the hyper-sphere, \(r = (\sum_{\mu=0}^{3} x_\mu)^{1/2}\), and respects the Lorentz covariant expression. See Ref. [30] for details. In contrast to the TMR explained above, the IR-cut in the CSS excludes the noise at large distance in all of \(t,x,y,z\) directions. Therefore, the CSS could achieve a better noise control, particularly for the quark disconnected contributions to the HVP, which are known to be notoriously noisy. So far, the CCS has been applied to the low energy running of the weak mixing angle [13].

3. Challenges

In the recent years, the LQCD has made significant progresses, particularly in the long distance and finite volume control, continuum extrapolations, and QED and strong isospin breaking (SIB) corrections, which will be reviewed in the followings.

3.1 Long distance control

As seen in Eq. (2.1), the typical scale \((m_\mu/(2hc))^{-1} \sim 4\) fm emerges from the kernel \(K(\hat{s})/m_\pi^2\) in the calculation of \(a^\text{LO-HVP}_{\mu}\). The light connected and disconnected correlators \((C^{f=ud}(t),D(t))\) in Eq. (2.5) includes 2-pion (isospin-one) contributions and some other light modes, and sizable contributions to \(a^\text{LO-HVP}_{\mu}\) remain at large distance of \(3-4\) fm. Even using many stochastic sources with AMA technique in the measurements, \(C^{ud}(t)\) and \(D(t)\) get strongly attenuated at \(t \gtrsim 3\) fm and need further elaborations in the precision \((\mathcal{O}(0.1)\) %) science of the \(a^\text{LO-HVP}_{\mu}\). To this end, one approximates the original LQCD data of \(C^{ud}(t)\) and \(D(t)\) at large distance \((t \gtrsim t_s)\) with modeling or reconstructing them so that the long distance properties are much better controlled than those in the original correlators. From a number of ideas proposed so far [1], we namely focus on the method using the time-like pion form factor proposed by the Mainz group [31].

We shall consider the isospin decomposition of the correlator (2.5) with finite spatial extension \(L\), \(G(t,L) = G^{I=1}(t,L) + G^{I=0}(t,L)\), and investigate the isospin-one part \(G^{I=1}(t,L)\) at large distance. In the spectral representation, it is expressed as

\[
G^{I=1}(t,L) = \sum_{n=1} |A_n|^2 e^{-\omega_n L}, \quad \omega_n^2 = 4(m_\pi^2 + k_n^2). \quad (3.1)
\]
We investigate the amplitudes $|A_n|$ and the energy levels $\omega_n$ via the Lüscher’s formula [32] in elastic cases and Meyer’s Formula [33],

$$\delta_{t=1}(k_n) + \phi \left( \frac{k_n L}{2\pi} \right) = n\pi, \quad \phi(z) = \frac{-z\pi^{3/2}}{(1/\sqrt{4\pi})\sum_{n\in\mathbb{Z}} (n^2 - z^2)^{-1}},$$

(3.2)

$$|F_\pi(\omega_n)|^2 = \frac{3\pi\omega_n}{2k_n^2} (\Delta\delta_1(k_n) + \Delta\phi(q_n)) |A_n|^2, \quad \Delta f(x) = \frac{df(x)}{d\log x},$$

(3.3)

as well as the Gounaris-Sakurai (GS) parametrization (c.f. Appendix of Ref. [34]),

$$\begin{cases}
\frac{k^3}{2\pi} \cot\delta_1(k) = k^2 h(\omega) - k^2 h(m_\rho) + (k^2 - k^2_\rho) b, \\
F_\pi(\omega) \sim F^\text{GS}_\pi(\omega) = \frac{1}{(k^3/\omega)\cot\delta_1(k)} \left( m_\pi^2 + k^2 h(m_\rho) + \frac{4\pi^2}{m_\pi^2} b \right),
\end{cases}$$

(3.4)

where $h(\omega) = (2k/(\pi\omega)) \log[(\omega + 2k)/(2m_\pi)]$, $\omega^2 = 4(m_\pi^2 + k^2)$, $k_\rho^2 = (m_\rho^2/4 - m_\pi^2)$, and $\Gamma_\rho$ represents a rho-meson decay width. For a given meson mass spectra $\{m_\pi, m_\rho\}$, the GS parametrization (3.4) allows us to express the p-wave phase shift $\delta_1(k_n)$ and the time-like pion form factor $F_\pi(\omega_n(k_n))$ as a function of the decay width $\Gamma_\rho$ and lattice momenta $k_n$. They are substituted into the Lüscher’s formula (3.2) and Meyer’s formula (3.3) to express $k_n$ and the amplitude $A_n$ as a function of $\Gamma_\rho$. Then, the isospin-one correlator (3.1) solely depends on the single unknown parameter $\Gamma_\rho$ and fitted to the original LQCD data of $G^{(1)}(t, L)$ to determine the $\Gamma_\rho$, and equivalently, $(k_n, A_n)$. The correlator $G^{(1)}(t, L)$ in Eq. (3.1) is now reconstructed with the obtained $(k_n, A_n)$.

The reconstructed-accumulated correlators [35] $G^{(1)}_{n=1}(t, L) = \sum_{j=1}^{n} |A_j|^2 e^{-\omega_0 t}$ multiplied by the weight function are displayed in Fig. 3. The lightest mode $n = 1$ becomes dominant at quite large distance around $t \sim 3$ fm, where the noise control of the original correlator is still challenging. In turn, the sum of the lightest three modes $(j = 1 - 3, n = 3)$ gives a good approximation of the original correlator around the peak ($\sim 1$ fm) and larger distance. For $t > x_0^{\text{cut}}$ in the figure, the accumulated correlators (e.g. $G^{(1)}_{n=4}(t, L)$) have much smaller uncertainty and give better estimates than the original one. The $G^{\text{LO-HVP}}_{n=1}(t, L)$ used at large distance becomes reliable and possesses a smaller statistical error. The systematic error is estimated by varying the threshold $x_0$.

In principle, the time-like pion form factor $F_\pi$ and the phase shift $\delta_1(\omega)$ can be directly measured in the LQCD without relying on the GS representation. In practice, however, one must investigate the energy spectra $\omega_n$ and the amplitudes $A_n$ by taking account of the pion scattering effects, which is challenging in finite volume Euclidean spacetime. In Ref. [36], the $(\omega_n, A_n)$ with rho meson resonance effects are extracted by solving the generalized eigen value problem for the pion-rho meson correlator matrices created with the distillation technique. Combined with the Lüscher (3.2) and the Meyer (3.3), one can determine the $(F_\pi, \delta_1(\omega))$ in the self-contained way within the

Figure 3: Reconstructed-accumulated correlators $G^{(1)}_{n=1}(t, L) = \sum_{j=1}^{n} |A_j|^2 e^{-\omega_0 t}$ multiplied by the weight function $(x_0 = t)$, quoted from Ref. [35].
LQCD. The reconstructed correlators in this method are recently studied by RBC/UKQCD collaboration [37]. Further advanced analyses are work in progress. Consider the Omnès formula: 

\[ F_\pi(\omega) = \exp(\omega^2 P_{n-1}(\omega^2) + (\omega^2/\pi) Q_n(\omega^2)) \] \[ Q_n(\omega^2) = \int_{4m^2_\pi}^{\infty} ds \delta_1(s) / \{ s^n (s - \omega^2 - i\epsilon) \} \]

For a selected subtraction level \( n \), the Polynomial \( P_{n-1} \) is determined by fitting the formula to the LQCD data of \( (F_\pi, \delta_1)(\omega) \), which is then obtained at arbitrary \( \omega \) without recourse to the GS parametrization [35].

The long distance behavior of \( C_{ud}(t) \) and \( D(t) \) is related to the FV effect estimates. We summarize the FV effects \( (\Delta_{\mu, ud}^{LO-HVP}(L_1, L_2) = d_{\mu, ud}^{LO-HVP}(L_2) - d_{\mu, ud}^{LO-HVP}(L_1), L_1 < L_2) \) estimated by several methods in Table 2. As argued in [24], the FV effects at sufficiently large distance would be governed by pions, in particular the \( I = 1 \) contributions (2-pion exchange with minimal lattice momentum \( 2\pi/L \)), which can be computed in the chiral perturbation theory (2-pion-XPT), which results in \( \sim 2\% \) correction to the total \( d_{\mu}^{LO-HVP} \) [21]. The FV effects taking account of more than the lowest 2-pion modes can be performed by using the time-like pion form factor \( F_\pi \); the infinite volume isospin-one correlator at large distance is expressed as, \( G_{\mu}^{\check{=}1}(t, L \to \infty) = (1/48\pi^2) \int_{2m_\pi}^{\infty} d\omega \omega^2 (1 - 4m^2_\pi/\omega^2)^{3/2} |F_\pi(\omega)|^2 e^{-\omega t} |, \) and comparing the \( d_{\mu}^{LO-HVP} \) obtained by \( G_{\mu}^{\check{=}1}(t, L) \) and \( G_{\mu}^{\check{=}1}(t, \infty) \) gives FV estimates including excited modes \( (n \geq 2) \). We call this method as Gounaris-Sakurai-Lüscher-Meyer (GSLM) method, which was proposed in the recent publication by Mainz group [31]. The RBC/UKQCD group has shown that the GSLM method gives 30% larger FV effects [37, 38] than the 2-pion-XPT for \((L_1, L_2) = (4.66, 6.22) \) fm. The ETM collaboration invented the dual QCD parametrization for the light-quark correlator in the intermediate scale [29] and its contribution to the FV effect is investigated in addition to the long distance contributions. This gives two times larger FV effects than the 2-pion-XPT estimate. Finally, the direct LQCD estimate gives even larger FV effects than any of above: \( \Delta_{\mu, ud}^{LO-HVP}(5.4 \text{ fm}, 10.8 \text{ fm}) = 40(18) \) [39] though the statistical error is large and has overlap to the other results. Thus, the FV effect tends to become larger by taking account of various mode contributions besides the lowest pion mode. \(^5\)

### 3.2 Extrapolation to continuum limit and physical mass point

In LQCD, simulations are carried out with finite lattice spacings \( (\alpha) \) and bare quark masses which do not reproduce the exact physical meson mass spectra at simulation points. It is challenging to control a continuum and a physical mass point extrapolations. HPQCD collaboration developed the pion-rho meson effective theory and derived formulas to calculate the lattice spacing \( (\alpha) \), taste breaking, and FV effects in the arbitrary order of the moments (2.10). Using the Padé approximants where the moments are the key quantities, they investigated the extrapolations of \( d_{\mu}^{LO-HVP} \) to the continuum and physical mass point. The left panel of Fig. 4 shows the physical mass point extrapolation of the light quark contribution to the anomaly \( d_{\mu, ud}^{LO-HVP} \) by the HPQCD [16]. The upper(lower) curves show their corrected(uncorrected) data: \( N_f = 2+1+1 \) HISQ ensembles, \( a = 0.15 \) (purple triangles), 0.12 (blue circles), and 0.09 fm (red squares). The corrected data become almost flat and stable against the extrapolation.

BMW collaboration performed simulations using \( O(10^2 - 10^4) \) stochastic source measurements with various lattice spacings ranging from 0.064 fm to 0.134 fm in a large volume \( 32L > 4 \) at almost physical quark masses for all ensembles \( (N_f = 2+1+1 \) staggered quarks, isospin limit, \( \bar{Q}_{ud-L}

\(^5\)In the 2-pion-XPT estimate for FV, 100% error-bar has been assigned, conservatively enough [21].
without QED) [21, 22]. With those high quality ensembles, it becomes possible to perform linear interpolations to the physical mass point (rather than the extrapolation) and well-controlled continuum extrapolations not only for quark-connected contributions (up/down, strange, charm), but also for up/down/strange-disconnected contributions. The fit functions are,

\[ F_{ud/disc} = a_{\mu,ud/disc}^{LO-HVP} (1 + A_{2}^{ud/disc} \alpha^2) , \quad F_{s} = a_{\mu,s}^{LO-HVP} (1 + A_{2}^{s} \alpha^2) + C \delta \tilde{m}_K^2 , \]

\[ F_{c} = a_{\mu,c}^{LO-HVP} (1 + A_{2}^{c} \alpha^2) + C \delta m_{\pi}^2 + C \delta m_{\eta} , \]

where \( \delta m_{\pi}^2 = m_{\pi}^2 - (m_{\pi}^{flag-isl})^2 \), \( \delta \tilde{m}_K^2 = \tilde{m}_K^2 - (\tilde{m}_{K}^{flag-isl})^2 \) with \( \tilde{m}_K^2 = m_{K}^2 - m_{\pi}^2 / 2 \), and \( \delta m_{\eta} = m_{\eta} - m_{\eta}^{hqcd} \). The suffix “flag-isl” indicates the isospin-limit value reported by the FLAG collaboration [40], and “hqcd” is the value reported by HPQCD collaboration (Appendix of Ref. [41]) in which the QED subtraction is taken care. The fit parameter \( a_{\mu,ud/disc}^{LO-HVP} \) is interpreted as each flavor contributions to the total \( a_{\mu,ud}^{LO-HVP} \) at the physical point up to SIB/QED corrections, which will be separately evaluated in later. The \( \chi^2 \), for example in the case of strange contributions, is given by

\[ \chi^2 = \langle t \Delta C^{-1} \Delta \rangle where t \Delta = (a - a_{dat}, \tilde{m}_{K} - \tilde{m}_{K}^{dat}, F_{s} - a_{\mu,s,dat}^{LO-HVP}) \] and \( C \) represents the covariance matrix constructed by \( (a_{dat}, \tilde{m}_{K}^{dat}, a_{\mu,l,s,dat}^{LO-HVP}) \). We note that \( (a_{\mu,l} \tilde{m}_{K}^2) \) in the \( \chi^2 \) and the fit function \( F_{c} \) denote fit parameters and not the lattice data themselves, and thus full correlations are taken account. The \( \chi^2 \) for the other flavors are constructed similarly, and a good fit quality is achieved for all connected and disconnected contributions. 6

In the right panel in Fig. 4, we show the continuum extrapolations by BMW collaboration [21]. The red-open-circles represent \( a_{\mu,ud}^{LO-HVP} \) without FV/taste corrections and are continuum-extrapolated to the red-filled-circle, for which FV effects estimated by 2-pion-XPT are added to get the final estimate (green-square, Fig. S4 in the supplemental material of Ref. [21]). This result is well agree to the blue-filled-triangle, which is obtained through the different procedure from the green-square; similarly to the HPQCD method [16], the FV and taste corrections estimated by the XPT with pions and rho-mesons are added to the red-open-circles and then continuum-extrapolated to get the blue-filled-triangle. The good agreement indicates the reliability of the results. The statistical and

---

6The fit functions may be modified from Eq. (3.5) in different ensembles by different LQCD groups: ① if non-staggard fermions without \( \partial(a) \) improvement are used, the fit function should include a term linearly dependent on \( a \), ② higher order terms of \( a \) might be necessary, ③ it might be necessary to correct ud-quark mistuning effects via \( m_{\pi}^2 \log m_{\pi}^2 \) term, ④ if ensembles do not include charm sea-quarks, the \( \Delta m_{\eta} \) term in \( F_{c} \) becomes irrelevant.
systematic uncertainties in the light component continuum extrapolations are both \( \sim 1.2\% \), which must be further reduced to achieve the target precision.

### 3.3 Strong-Isospin Breaking and QED corrections

For the target precision \( \mathcal{O}(0.1\%) \), the strong-isospin breaking (SIB, \( \mathcal{O}(\delta m/L_{\text{QCD}}) \sim 1\% \), \( \delta m = m_d - m_u = 2.41(6)(4)(9) \text{ MeV} \) in MS-2 GeV [42]) and QED (\( \mathcal{O}(\alpha) \sim 1\% \)) corrections must be taken account. For SIB, three different strategies have been considered; \( \circ \) direct LQCD simulations where the input up and down quark masses set different, \( \circ \) use isospin symmetric ensembles and the SIB effects are encoded in the valence quarks in observable measurements, \( \circ \) use isospin symmetric ensembles and perform a perturbative expansion in terms of \( \delta m = m_d - m_u \) [43].

The first and second methods were recently adopted by FHM collaboration [44]; the muon anomaly \( a_{\mu}^{\text{LO-HVP}} \) was calculated for both \( N_f = (1+1+1) \) and \( (2+1+1) \) ensembles with almost physical up and down quark masses, and a valence quark mass \( (m_{\text{val}}) \) dependence of \( a_{\mu}^{\text{LO-HVP}} \) was compared between them.

Two results agree at \( m_{\text{val}} = m_l = (m_u + m_d)/2 \), which indicates the SIB effects in sea-quarks (included in \( \circ \) only) are negligible. The SIB correction is then approximated by \( \delta a_{\mu}^{\text{LO-HVP}} = (q_u^2 a_{\mu}^{\text{LO-HVP}}|m_u + q_d^2 a_{\mu}^{\text{LO-HVP}}|m_d) - (q_u^2 + q_d^2 a_{\mu}^{\text{LO-HVP}}|m_l \) where the charge factors \( q_{u,d} \) are defined in Eq. (2.4). The result by FHM group [44] is: \( \delta a_{\mu}^{\text{LO-HVP}}/a_{\mu}^{\text{LO-HVP}} = 1.5(7)\% \) (positive).

We shall move on the perturbative method \( \circ \) [43]. Let \( S \) be the QCD action with SIB effects. The up/down mass terms \( (m_u \bar{u}u + m_d \bar{d}d) \) in \( S \) is rewritten as \( m_l (\bar{u}u + \bar{d}d) - \delta m (\bar{u}u - \bar{d}d) \) with \( m_l = (m_u + m_d)/2 \) and \( \delta m = (m_d - m_u)/2 \). Therefore, one find \( S = S_0 - \delta m S_{\text{br}} \) where \( S_0 \) denotes the isospin symmetric part and \( S_{\text{br}} = \sum_{l} (\bar{u}u - \bar{d}d)(x) \) represents the breaking term. Consider the ensemble average of an operator \( \mathcal{O} \) and expand it in terms of \( \delta m: \langle \mathcal{O} \rangle = \int O e^{-S}/\int e^{-S} \approx \int \left[ 1 + \delta m S_{\text{br}} \right] e^{-S_0} \approx \langle \mathcal{O} \rangle_0 + \delta m \langle OS_{\text{br}} \rangle_0 \), where \( \langle \cdot \rangle_0 \) represents the ensemble average with the isospin symmetric weight \( e^{-S_0} \). This method allows us to reuse existing isospin-symmetric ensembles to evaluate the SIB effect. In the present context, \( O = G_{\mu\nu}(t) \) (c.f. Eq. (2.3)), and the Wick theorem tells us that the SIB term \( \delta m \langle G_{\mu\nu}(x)S_{\text{br}} \rangle_0 \) produces the diagrams shown in Fig. 5. RBC/UKQCD collaborations [45] has shown that the perturbative method is consistent with the quark mass method \( \circ \). At the physical mass point, the perturbative method is shown to give the 1.5(1.2)\% positive correction to the total \( a_{\mu}^{\text{LO-HVP}} \) [19], consistently to the FHM group mentioned above.

We shall now investigate the (QCD + QED) system for which the partition function reads, \( \langle \mathcal{O} \rangle = (1/Z) \int_{\mathcal{A}} \int_{\bar{q}_0} \int_{\bar{d}_0} \int_{\bar{u}_0} O e^{\mathcal{S}_0[\bar{q},\bar{d},\bar{u},\mathcal{A}] - \mathcal{S}_0[\bar{q}] - \mathcal{S}_0[\mathcal{A}]} \), with \( O = G_{\mu\nu}(t) \) (c.f. Eq. (2.3)) in the present context. To ensure the transfer matrix well-defined, the non-compact QED \( (\mathcal{S}_T[\mathcal{A}] = (a^4/4)(\sum_{\mu} \tilde{\partial} \cdot A_{\mu})^2) \) is usually adopted in the Coulomb gauge \( \langle \tilde{\partial}^+ \cdot \mathcal{A} \rangle = 0 \). To control QED FV effects, QED\textsubscript{L} prescription [46] is used; spatial zero-modes and the universal \( 1/L^{n=1.2} \) corrections to mass are removed, while a reflection positivity is preserved.

There are several strategies to include the QED effects; \( \circ \) phenomenological estimates based on the dispersive method and XPT [21, 22], \( \circ \) direct lattice simulations for the above partition function, which is, at this moment, available for \( m_\pi = 400 \text{ MeV} \) case [47], \( \circ \) stochastic method [48] where the photon fields \( A_{\mu} \) in the quark determinant are ignored and stochastically
generated with weight $e^{-S_F}$ independently of gluon fields $U_\mu$ (electro-quenched), and multiplied, $U_\mu(x) \rightarrow e^{-ieq/A_\mu(x)}U_\mu(x)$. (2) perturbative method where QED is treated in the perturbative expansion in $\alpha = e^2/(4\pi)$ [49]. $\langle G_{\mu\nu} \rangle = \langle G_{\mu\nu} \rangle_0 + \frac{e^4}{2} \frac{\partial^2 \langle G_{\mu\nu} \rangle}{\partial e_{el}^2} \bigg|_{e_{el}=0} + \mathcal{O}(\alpha^2)$, where $\langle \cdot \rangle_0 = \langle \cdot \rangle|_{e_{el} \rightarrow 0}$. The derivative $\partial \langle \cdot \rangle / \partial e_{el}$ picks up a combination of a photon $A_\mu$ and a vector current operators $j_\mu$ from $e^{-S_F[q,\bar{q},U,A]}$ and $e_{el} \rightarrow 0$ taken after. Therefore, the QED corrections are expressed as $A_\mu$ and $j_\mu$ insertions to the quenched average $\langle G_{\mu\nu} \rangle_0$. In additions, a mass retuning due to QED inclusion is necessary via the scalar operator insertion. If the twisted mass boundary condition is used, the pseudo-scalar operator insertion is also necessary to keep the twist originally set. Various diagrams with the insertions are displayed in the left panel of Fig. 6.

The right panel in Fig. 6 is the result by ETM group [51] and shows the SIB and QED corrections in the light quark anomaly $\alpha_{LO-HVP}^{\mu,ud}$ as a function of the renormalized mass. The open and filled symbols corresponds to the raw and FV-corrected LQCD data, respectively. The solid line shows the fit for the corrected data and gives the correction at the physical point (black asterisk), which is around 1% correction with a few per-mil uncertainty ($\delta \alpha_{LO-HVP}^{\mu,ud} \times 10^{10} = 7(2)$). In Table 1, the SIB/QED corrections are summarized. All results are $\sim \mathcal{O}(1)\%$ and consistent within relatively large error-bars, which must be reduced with respect to the target precision $\mathcal{O}(0.1)\%$ in future.

3.4 Other developments

There are many subjects which are related to the HVP and $\alpha_{LO-HVP}^{\mu,ud}$ but omitted in this proceedings. See the following references: LQCD study on the isospin breaking in tau decay and muon $g - 2$ [52], LQCD combined with MUonE experiments [12, 29], NLO-HVP contributions to muon $g - 2$ [17], LO-HVP contribution to the weak-mixing angle [13], CKM matrix element $|V_{us}|$ from LQCD (V + A) current correlators [53].

---

7Besides the diagrams shown in Fig. 6, the QED correction to the strong coupling constant would be necessary. See Ref. [50] for details.
4. Comparison and Discussion

This section is devoted to show $a_{\mu}^{\text{LO-HVP}}$ reported by various LQCD groups and compare them. The combined results using the LQCD and the dispersive method are also discussed. The $a_{\mu}^{\text{LO-HVP}}$ to be compared takes account of the extrapolations to the continuum limit and the physical mass point, and FV/SIB/QED corrections. The uncertainties include a statistical error and systematic errors from a scale setting, lattice data cuttings, fit model dependences in the extrapolations/interpolations, IR-cuts in the correlators $C^{f=ud}(D)(t)$, and/or UV-cuts in the HVP $\hat{\Pi}(\omega^2)$. Both statistical and total systematic errors are at a few percent level at present.

4.1 Comparing LQCD results

In Fig. 7 and Table 3, we compare $a_{\mu}^{\text{LO-HVP}}$ reported by various LQCD groups as well as the one from the dispersive method. The recently published results, BMW-18 [21] and RBC/UKQCD-18 [19], are consistent well to each other and no new physics (green band in the figure): the value that $a_{\mu}^{\text{LO-HVP}}$ would have to explain the experimental measurement of $a_{\mu}$ [3], assuming that all other SM contributions are unchanged. In contrast, HPQCD-17 [16], ETM-14 [54], and ETM-18 [29] have observed a smaller $a_{\mu}^{\text{LO-HVP}}$ than no new physics. Recently, HPQCD-17 is updated to FHM-prelim., which becomes closer to the BMW-18 and RBC/UKQCD-18 estimates. All (updated) results are consistent with the dispersive estimates where the latter uses Eq. (1.2) to calculate the HVP. Thus, the present LQCD estimates of $a_{\mu}^{\text{LO-HVP}}$ are still premature to confirm or infirm the deviations among the experimental measurement and the dispersive SM predictions.

As seen in Fig. 7, the LQCD published results are not fully consistent to each other. To see how the tension comes out, we compare $a_{\mu}^{\text{LO-HVP}}$ in flavor-by-flavor in Fig. 8 (see also Table 4): connected light/strange/charm contributions ($a_{\mu,\text{conn}}^{\text{LO-HVP}}$, upper-left/lower-left/upper-middle) and disconnected contributions ($a_{\mu,\text{disc}}^{\text{LO-HVP}}$, lower-middle). The $a_{\mu,\text{conn}}^{\text{LO-HVP}}$ are already determined with high enough precision with respect to the requirements from FNAL-E989 and J-PARC-E34 experiments and consistent among all LQCD groups. The tension is on the light connected contribution $a_{\mu,\text{ud}}^{\text{LO-HVP}}$ in the published results as shown in the upper-left panel. FHM collaboration has updated their ensembles and improved the multi-exponential fits for the light quark connected correlator $C^{\text{ud}}(t)$ at large distance, which modified their result to $a_{\mu,\text{ud}}^{\text{LO-HVP}} = 630(8)$ [55]. In turn, $a_{\mu,\text{ud}}^{\text{LO-HVP}}$ by RBC/UKQCD tends to become smaller when the higher excitation modes are taken account in the improved bounding method for $C^{\text{ud}}(t)$ at large distance [37]. Thus, the tension in $a_{\mu,\text{ud}}^{\text{LO-HVP}}$ seems related to the treatment of the long distance behavior in $C^{\text{ud}}(t)$ and relaxed in the updated results.

---

8It should be noted that the discrepancy in the $a_{\mu,\text{ud}}^{\text{LO-HVP}}$ between HPQCD-17 and the others (upper-left panel in Fig. 8) is somewhat overestimated; the FV and taste-breaking corrections from the disconnected pion contributions are included in HPQCD-17 (due to some methodological reason) while not in the results from the others.
Figure 8: Comparison in flavor-by-flavor: connected light/strange/charm contributions \(a_{\mu,\text{con}}^{\text{LO-HVP}}\) (upper-left/lower-left/upper-middle) and disconnected contributions \(a_{\mu,\text{disc}}^{\text{LO-HVP}}\) (lower-middle). The right-most panels show the first (upper) and second (lower) time-moments with light components \((\Pi^\text{ind}_{1,2})\), see Eq. (2.10)).

We shall consider the \([1, 1]\) Padé approximants (c.f. Sec. 2.2) for the HVP \( \Pi \), and then the light-connected anomaly is evaluated as 

\[
a_{\mu,\text{con}}^{\text{LO-HVP}}(t) = (\alpha/\pi)^2 \int_0^\infty dQ^2 \omega(Q^2/m_H^2) Q^2 \Pi_{1,2}^{\text{ind}} / (1 - Q^2 / \Pi_{1,2}^{\text{ind}})
\]

where the moments \(\Pi_{1,2}^{\text{ind}}\) are obtained from the LQCD data (see, Eq. (2.10)). In Padé, smaller \(\Pi_1\) and larger \((-\Pi_2)\) result in a smaller \(a_{\mu,\text{con}}^{\text{LO-HVP}}\). This explains how the tension in \(a_{\mu,\text{con}}^{\text{LO-HVP}}\) comes out as shown in the right-most panels of Fig. 8 (see also Table. 5). HPQCD-17 [16] has smaller \(\Pi_1\) and larger \((-\Pi_2)\) than those by BMW-17 [22] and RBC/UKQCD-18 [19].

4.2 Lattice combined with dispersive method

The combination of the LQCD and dispersive method may deliver the estimates of \(a_{\mu,\text{con}}^{\text{LO-HVP}}\) at a per-mil level close upon the target precision. The left panel of Fig. 9 shows the integrand in Eq. (2.9) for LQCD data by BMW-18 [19] and the dispersive method: 

\[
G_{\text{lat/ph}}(t) W(t, \omega^2/\mu^2)
\]

The suffix “lat” and “ph” show LQCD and phenomenological vector current correlators, respectively, where the latter is defined via the R-ratio (c.f. Eq. (1.2)). 

\[
G_{\text{ph}}(t) = (1/2) \int_0^\infty ds \sqrt{2R(s)} e^{-\sqrt{s}|t|}
\]

In the left panel, a peak is around \(t \sim 1\) fm, where the LQCD data would not suffer from the discretization nor FV artifacts and are determined more precisely than the dispersive method. RBC/UKQCD group has proposed [19] that the \(G_{\text{lat}}(t)\) is used for that region \((t \sim 1\) fm) while the dispersive data are adopted for the UV and IR regions. Consider the decomposition,

\[
G_{\text{lat/ph}}(t) = G_{\text{lat/ph}}^{\text{SD}} + G_{\text{lat/ph}}^{\text{W}} + G_{\text{lat/ph}}^{\text{LD}}(t)
\]

(4.1)

\[
(G_{\text{lat/ph}}^{\text{SD}}, G_{\text{lat/ph}}^{\text{W}}) = G_{\text{lat/ph}}(t)/(1 - \Theta(t, t_0, \Delta), \Theta(t, t_0, \Delta) - \Theta(t, t_1, \Delta), \Theta(t, t_1, \Delta))
\]

(4.2)

with the smeared step function, \(\Theta(t, t', \Delta) = 0.5(1 + \tanh[(t - t')/\Delta])\). The light-blue and green lines in the right panel of Fig. 9 represent \(G_{\text{ph}}^{\text{SD}}(t, \Delta) W(t, \omega^2/\mu^2)\) and \(G_{\text{ph}}^{\text{LD}}(t, \Delta) W(t, \omega^2/\mu^2)\), respectively. The missing contribution (difference between (light-blue + green) and purple lines) is compensated by LQCD data \(G_{\text{lat}}^{\text{SD}}(t, \Delta) W(t, \omega^2/\mu^2)\). Thus, lat/pheno-combined estimate is

\[
a_{\mu,\text{cmb}}^{\text{LO-HVP}}(t_0, t_1, \Delta) = \int_0^\infty dt G_{\text{SD}}(t, \Delta) W(t, \omega^2/\mu^2) + \sum_{t'=0}^t G_{\text{Lat}}(t, \Delta) W(t, \omega^2/\mu^2) + \sum_{t=0}^\infty dt G_{\text{ph}}(t, \Delta) W(t, \omega^2/\mu^2)
\]
The window threshold parameters \((t_0, t_1)\) are adjusted to minimize a total uncertainty and their variation gives a systematic error. A finite smearing parameter \(\Delta\) is adjusted to control the lattice discretization artifact at the window boundary. RBC/UKQCD used \((t_0, t_1, \Delta) = (0.4, 1.0, 0.15)\) fm and obtained \(a_{\text{LO-HVP}}^{\mu, \text{comb}} = 692.5(2.7) \cdot 10^{-10}\) \([19]\), which may be the most precise estimate today.

In Ref. [56], the window method is considered with the same \((t_0, t_1, \Delta)\) as the above and the contribution from the intermediate window is evaluated by using two different LQCD ensembles: HISQ or domain-wall fermions (DWF). In the continuum limit, the DWF becomes consistent with the dispersive method while the HISQ gets larger than them. The discrepancy is about 2-\(\sigma\). We need more studies on the discretization effects in the window method.

5. Concluding remarks

We have reviewed the LQCD results for the hadron vacuum polarization (HVP) and its leading-order \((\sim \mathcal{O}(\alpha^2))\) contribution to the muon anomalous magnetic moments \(a_{\mu, \text{LO-HVP}}^{\mu}\). Remarkably enough, more than 3-sigma deviations between the standard model (SM) prediction with the QCD dispersion relation used for HVP and the BNL experiment in 0.5 ppm precision is reported. This may be a milestone to the BSM physics while it is mandatory to confirm or infirm the discrepancy based on the ab-initio calculation by the lattice QCD (LQCD) simulations. In the coming years, FNAL-E989, J-PARC-E34, and MUonE experiments will provide more precise data, which requires the LQCD to give the \(a_{\mu, \text{LO-HVP}}^{\mu}\) with a precision at \(\mathcal{O}(0.1)\) % level.

Significant progresses have been made in the LQCD approaches to \(a_{\mu, \text{LO-HVP}}^{\mu}\), particularly in the long distance and finite volume (FV) control, continuum/chiral extrapolations, and QED and strong isospin breaking (SIB) corrections. HPQCD group invented the pion/rho-meson effective theory applied to the Taylor coefficients of the HVP and investigated the IR property of the HVP to control the physical mass point extrapolations [16]. The BMW group generated high quality ensembles at almost physical quark masses with fine lattice spacings in large boxes, and determined the continuum limit of \(a_{\mu, \text{LO-HVP}}^{\mu}\) with \(\sim 1.2\) % accuracy in both statistical and systematic uncertainties [21].
The FV and SIB/QED corrections are summarized in Tables 2 and 1, respectively. The statistical and systematic errors must be further reduced in future.

Table 3 and Fig. 7 provides the summary of the $a_{\mu,\text{LO-HVP}}^\text{r}$. For a fair comparison, the extrapolations to the continuum limit and the physical mass point with FV/SIB/QED corrections have been taken. The uncertainties include a statistical error and systematic errors from a scale setting, lattice data cuttings, fit model dependences in the extrapolations/interpolations, IR-cuts in the correlator, and/or UV-cuts in the HVP. Both statistical and total systematic errors in LQCD are at a few percent level, which is still much larger than the dispersive estimates. The large portion of the uncertainty and some disagreements among the LQCD estimates are on the light connected contributions $a_{\mu,\text{ud}}^\text{LO-HVP}$, and presumably originate to the long distance control of the correlators with light components. The $a_{\mu,\text{s/c/disc}}^\text{LO-HVP}$ are already determined with high enough precision and consistent among various LQCD groups. The window method based on the coordinate space expression allows a combined analyses using both LQCD and dispersive method and could deliver the estimates of $a_{\mu}^\text{LO-HVP}$ at a per-mil level close upon the target precision.

As a future perspective, the following developments are work in progress; 1⃝ significantly improved statistics with continuously increasing ensembles and a better noise control, 2⃝ much better understandings of the light connected correlators at large distance and FV effects via the LQCD data driven estimates for the time-like pion form factor [37, 36] together with the improved bounding method [37, 38], 3⃝ precise estimates of SIB/QED corrections in the stochastic method combined with the perturbative expansion in $\alpha = e^2_{e\ell}/(4\pi)$ and $\delta m = m_d - m_u$ [57]. The next step required for the LQCD is to establish the consensus among various LQCD estimates of the $a_{\mu,\text{ud}}^\text{LO-HVP}$ with a per-mil precision based on the aforementioned progresses, which would be achieved within a few years and have an important indication for the FNAL-E989, J-PARC-E34, and MUnE experiments with respect to exploring the BSM.

Acknowledgments The author thanks to the organisers of the lattice conference 2018 for the invitation to the plenary talk and the accommodation during the conference. He thanks to GSI for the financial support for his travel to the conference site (Michigan-USA). He thanks for fruitful discussions to H. Wittig, H. Meyer, A. Risch, L. Lellouch, B. Tóth, C. Davies, R. Water, C. Lehner, V. Gülpers, A. Meyer, S. Simula, D. Giusti, M. Marinkovic, T. Blum, and J. Zanotti.

Table 3: Summary of $a_{\mu}^{\text{LO-HVP}}$. See also Fig. 7. In the second column, “$N_f = 2+1$” takes account of a charm quark in valence quarks but not in sea-quarks. In $N_f = 2$, a strange quark effect in sea-quarks is also missing. The first and second brackets show statistical and systematic errors, respectively. In the case with only one bracket, it includes both errors. HISQ = highly improved staggered quarks, Stout4 = 4 steps stout-smeared staggered quarks, tmQCD = twisted mass QCD, DWF = domain wall fermions, Clover = $\mathcal{O}(a)$ improved Wilson quarks. For the staggered quarks, a rooting technique is used. TMR = time-momentum representation, VMD = vector-meson dominance.
