Abstract. To examine whether spermidine (SPD) modifies plant antioxidant enzyme expression in response to short-term salt stress, cucumber (Cucumis sativus) seedlings were treated with NaCl in the presence or absence of SPD for 3 days. Compared with untreated control plants, free radical production and malondialdehyde content in leaves and roots increased significantly and plant growth was suppressed under 50 mM NaCl stress. Exogenous SPD sprayed on leaves at a concentration of 1 mM alleviated salinity-mediated growth reduction. Salt stress caused a consistent increase in soluble protein content, as well as peroxidase (POD) and superoxide dismutase (SOD) activities in cucumber seedlings. By native polyacrylamide gel electrophoresis, five POD isozymes were detected in cucumber seedling leaves, and seven in roots. We detected five SOD isozymes in leaves and four in roots, and two catalase (CAT) isozymes in leaves and two in roots. Our results indicate that salt stress induced the expression of POD and SOD isozymes in cucumber seedlings, but inhibited the expression of CAT isozymes in roots. Application of exogenous SPD further increased POD and SOD expression and activity, and led to the differential regulation of CAT in leaves and roots. These data show that antioxidant enzymes, especially POD and SOD, appear to protect cucumber seedlings against stress-related damage, and they appear to function as the molecular mechanisms underlying the response of cucumber seedlings to salinity. Moreover, SPD has potential to scavenge directly free radical and to alleviate growth inhibition and promote the activity and expression of antioxidant system enzymes in cucumber seedlings under short-term salt stress.

The recent overutilization of chemical fertilizers has caused secondary salinization in Chinese greenhouses, and salinity is one of the major environmental factors limiting plant growth and yield (Parida and Das, 2005). The large accumulation of salt and salt ions may induce biochemical changes in greenhouse plants, such as the accumulation of reactive oxygen species (ROS). This accumulation will increase the level of oxidized species, thereby creating oxidative stress that can damage DNA, inactivate enzymes, and cause lipid peroxidation (Finkel and Holbrook, 2000; Moldovan and Moldovan, 2004). The most important forms of ROS are hydroxyl radicals, singlet oxygen, superoxide radicals, and hydrogen peroxide (H₂O₂). Plants possess an endogenous mechanism to protect cellular and subcellular systems from the cytotoxic effects of ROS, which includes low-molecular-weight non-enzymatic antioxidants and enzymatic components (Agarwal and Pandey, 2004).

Superoxide dismutase (SOD) is a metalloprotein that catalyzes the dismutation of superoxide radicals to H₂O₂ and O₂ (Bowler et al., 1992). The H₂O₂ is then scavenged by catalase (CAT) and a variety of peroxidases (POD) and converted into H₂O and O₂. The biochemical defense system also includes nonenzymatic constituents, such as glutathione, ascorbic acid, α-tocopherols, and carotenoids (Apel and Hirt, 2004). In recent years, growing interest has focused on the idea that the regulation of these antioxidants by an exogenous substance might mediate plant tolerance to salt stress.

Polyamines (PAs) are low-molecular-weight aliphatic amines that are ubiquitous in all organisms. Common natural PAs include the higher PAs, spermine (SPM) and spermidine (SPD), and their diamine obligate precursor putrescine (PUT). These PAs are absolutely necessary for normal cell growth. At physiological pH, PAs have been shown to influence protein synthesis, DNA-protein interactions (van den Broeck et al., 1994), and membrane integrity (Tiburcio et al., 1994). In plants, PAs are believed to play an important protective role against various environmental stresses, such as osmotic stress, salinity, heat, chilling, hypoxia, and mineral nutrient deficiencies (Bouchereau et al., 1999). Among the three major PAs (SPM, SPD, and PUT), SPD has, in many cases, been most closely associated with stress tolerance in plants (Kasukabe et al., 2004; Shen et al., 2000). Shen et al. (2000) sprayed cucumber leaves with 1 mM PAs (PUT, SPD, or PUT) and found that SPD prevented chill-induced superoxide formation and CI. Exogenous 1 mM SPD sprayed on maize (Zea mays) leaves could alleviate the effect of NaCl (Jiang et al., 2000). SPD application to salinized nutrient solution resulted in an increase in polyamine and proline contents and antioxidant enzyme activities in cucumber seedlings, which contributed osmotic adjustment.
during salinity (Duan et al., 2008). In water-stressed cucumber plants, Kubiš (2008) showed that exogenous application of SPD with 1 mM concentration, due to a higher concentration (3 mM) with negative influence and lower (0.1 mM) with very limited effect, moderated the activities of scavenging system enzymes and influenced oxidative stress levels.

Cucumber is one of the most important vegetables worldwide. It is highly sensitive to salinity, especially during germination and in the early stages of development (Bayosal and Tipirdamaz, 2007). The effect of SPD on isoforms of antioxidant enzymes (SOD, POD, and CAT) in cucumber seedlings treated with NaCl is unknown. To answer this question, leaves and roots were harvested from treated and untreated plants to measure growth, antioxidant enzyme activity, and isozyme expression. The objective of the present study was to assess the influence of SPD sprayed on leaves on the activity of antioxidant enzymes and isoforms in cucumber seedlings subjected to short-term salt stress. In addition, isoforms and other genetic information regarding horticulturally important traits may be useful for defining a cucumber core collection.

Materials and Methods

Cucumber (cv. Jinchun No.2) seeds were germinated on moist filter paper in the dark at 28 °C for 30 h. The germinated seedlings were transferred to plastic trays (41 × 41 × 5 cm) containing quartz sand and were grown in a greenhouse at Nanjing Agricultural University at 25 to 30 °C day/15 to 18 °C night under natural light. Relative humidity in the greenhouse ranged between 60% and 75%. When the cotyledons expanded, seedlings were supplied with water containing one-half-strength Hoagland’s nutrient solution (pH 6.5 ± 0.1, EC 2.0–2.2 dS·m⁻¹). After full development of the third leaf of each plant, 12 seedlings of uniform size were transplanted into each of three plastic containers (51 × 33 × 20 cm) filled with full-strength Hoagland’s nutrient solution and renewed every 2 d. The nutrient solutions were kept at 20 to 25 °C and were continuously aerated using an air pump at an interval of 20 min to maintain the dissolved oxygen at 8.0 ± 0.2 mg·L⁻¹.

After 3 d of pre-culture, the treatments were started. The cucumber seedlings were treated as follows: 1) control plants were grown in Hoagland’s solution, 2) salt-treated plants were grown in Hoagland’s solution plus 50 mM NaCl, and 3) supplemental SPD plants were grown in Hoagland’s solution plus 50 mM NaCl and the leaves were sprayed with 1 mM SPD. The leaves of the control and salt-treated plants were sprayed with distilled water. Tween-20 (0.5%, v/v) was used as surfactant. Three days after beginning NaCl treatment, the fully expanded third leaves and the middle part of roots were harvested, immediately frozen in liquid nitrogen, and stored at −80 °C until required for analyzing free radical production, malondialdehyde (MDA) content, enzyme assay, and isozyme analysis.

The area of the third and fourth leaf, total root length, and number of root tips on a plant were measured using a scanner (Expression 1680; Epson America, Long Beach, CA) and image analysis software WinRHIZO (Regent Instruments, Quebec, QC, Canada). Before determination of fresh weight, the seedlings were uprooted from the culture medium and washed using deionized water. Shoots and roots were separated. After measuring the fresh weight, samples were dried in an oven at 105 °C for 15 min followed by 75 °C for 72 h, and the dry weight was then measured. Relative growth rate (RGR) was defined as the parameter RGR in the equation (Hunt, 1990):

\[ RGR = \frac{\ln(W_2) - \ln(W_1)}{t_2 - t_1}. \]

W1 and W2 are the whole plant fresh weights at times t1 and t2.

For enzyme activities, samples (1 g) were harvested directly into liquid nitrogen and homogenized in 1.0 L of extraction buffer (50 mM PVP, 1 mM PMSF, 10 mM DTT, and 0.1 mM EDTA, in 50 mM potassium phosphate buffer, pH 7.8). The homogenate was centrifuged at 19,000 g for 20 min at 4 °C, and the supernatant was re-centrifuged again at 19,000 g for 20 min at 4 °C for determination of enzyme activities. The protein concentration of the enzyme extract was determined according to the Bradford (1976) method using bovine serum albumin as a standard.

POD activity was measured according to the method of Kochba et al. (1977). One unit of activity was defined as the amount of enzyme required to increase the optical density at 470 nm·min⁻¹ by 1 absorbance unit. SOD and CAT activity was assayed according to Dhindsa et al. (1981). One unit of SOD activity was defined as the amount of enzyme required to cause 50% inhibition of the photochemical reduction of nitroblue tetrazolium (NBT) and was monitored at 560 nm. One unit of CAT activity was defined as the amount of enzyme required to decrease the optical density at 240 nm·min⁻¹ by 0.1 absorbance units.

Native polyacrylamide gel electrophoresis (PAGE) was performed at 100 V for 60 min at 4 °C, and then at 200 V for ∼180 min. Electrophoresis buffer and gels were prepared as described by Laemmli (1970), with the exception that sodium dodecyl sulfate was excluded. The activity stain for each enzyme was carried out as described below. To separate CAT isoforms, native PAGE was performed using 7.5% polyacrylamide gels. CAT was visualized on the gel using the method of Woodbury et al. (1971). After electrophoretic separation, the gel was incubated in 0.003% H₂O₂ for 10 to 15 min, washed with distilled water twice, and then incubated for 5 to 10 min in 1% ferric chloride and 1% potassium ferricyanide. After staining, the gel was carefully washed with tap water. To separate POD isoforms, native PAGE was performed using 7.5% polyacrylamide gels. POD isoforms were detected in gels as reported by Fielding and Hall (1978). The gel was incubated in a reaction buffer containing 25 mM potassium buffer (pH 7.0) for 15 min to lower the pH. The gel was submerged again in a freshly prepared solution of 18 mM guaiacol and 25 mM H₂O₂ in 25 mM potassium phosphate buffer (pH 7.0) until the POD isozyme bands could be visualized. To separate SOD isoforms, native PAGE was performed using 10% polyacrylamide gels. SOD activity was detected by the procedure described by Beauchamp and Fridovich (1971). The gel was equilibrated with 36 mM potassium phosphate buffer (pH 7.8) containing 2.8 × 10⁻⁵ M riboflavin and 0.028 M N,N,N’,N’-tetramethylethylenediamine for 30 min. The gel was washed in distilled water for 1 min and submerged with gentle agitation for 10 to 20 min in the same buffer as above containing 2.45 mM NBT. In the presence of light, the enzymes appeared as colorless bands on a purple background. All gels were then photographed.

Lipoxygenase (LOX) activity was measured spectrophotometrically according to a slight modification of the procedure
Results

GROWTH. In the present study, the fourth leaf area, shoot dry weight, root length, root dry weight, and RGR were significantly decreased 3 d after starting NaCl treatment ($P < 0.05$) compared with the control. Application of exogenous SPD (sprayed on leaves) alleviated the salinity-mediated growth reduction (Table 1).

FREE RADICAL PRODUCTION AND MEMBRANE DAMAGE. Compared with the control, $O_2^-$ production rate, $H_2O_2$ content, and MDA content increased significantly under salt stress. LOX activity in roots increased under salt stress, but decreased significantly in leaves. Exogenous SPD sprayed on leaves reduced salinity-induced free radical production and membrane damage, which was greater in roots than in leaves (Table 2).

SOLUBLE PROTEIN CONTENT AND ANTIOXIDANT ENZYME ACTIVITIES. As shown in Table 2, leaves contained protein levels eight times higher than those in roots. Under salt stress, root protein content was significantly increased (by 40%) compared with the control, and leaf protein content was increased by 14%. Application of exogenous SPD further elevated the protein content present in leaves, but slightly decreased the level in roots. Compared with the control, CAT activity in leaves increased 3 d after starting NaCl treatment ($P < 0.05$), and exogenous application of SPD further increased the activity. CAT activity in roots exhibited an opposite trend. Salt stress created different effects on POD activity. On the third day after treatment, salt stress greatly induced POD activity in roots and leaves ($P < 0.05$), and exogenous SPD further enhanced the induction of POD activity. Similar to POD, salt stress promoted the activity of SOD in cucumber seedling roots and leaves, and this effect was enhanced by application of exogenous SPD.

SOD, POD, AND CAT ISOZYMES. POD (Fig. 1), SOD (Fig. 2), and CAT (Fig. 3) isozymes of leaves and roots in cucumber seedlings were examined 3 d after starting treatment. Root POD activity (Table 2) was significantly higher than that in leaves, and a similar phenomenon was observed in POD isozyme profiles (Fig. 1). POD was present as five isozymes and seven isozymes in leaves (Fig. 1A) and roots (Fig. 1B), respectively. During the separation of these isozymes in native PAGE gels, we observed that POD isozymes were very susceptible to NaCl treatment in the presence and absence of SPD. In leaves (Fig. 1A), salt stress significantly increased the expression of all five POD isozymes (L-P1, L-P2, L-P3, L-P4, and L-P5). Exogenous SPD further increased the expression of L-P3, L-P4, and L-P5, but decreased L-P1 and L-P2. In roots, R-P1, R-P2, R-P3, R-P5, R-P6, and R-P7 bands appeared to increase significantly in response to salt stress (Fig. 1B) compared with the control. Exogenous SPD enhanced the L-P1, L-P4, L-P6, and L-P7 isozyme bands, and somewhat decreased the levels of L-P2 and L-P3. Remarkably, the R-P4 differed from those of other root POD isozymes in that it decreased in response to salt stress, and increased further in response to application of exogenous SPD.

We observed five SOD isozymes on native PAGE gels of cucumber seedling leaves (Fig. 2A). These bands were identified as L-S1, L-S2, L-S3, L-S4, and L-S5, and had relative mobility ($R_f$) values of 0.358, 0.368, 0.637, 0.743, and 0.782, respectively. The L-S4 band was the strongest band, while the L-S2 and L-S5 bands were weakest. With the exception of L-S5, all SOD isozymes were enhanced by NaCl treatment. Exogenous SPD sprayed on leaves inhibited the L-S4 and L-S5 bands, and enhanced the L-S1, L-S2, and L-S3 bands. Compared with the control, four SOD isozyme bands (R-S1, R-S2, R-S3, and R-S4) present in roots (Fig. 2B) were enhanced by NaCl stress, and all four were further enhanced by SPD application.

Figure 3A shows that two CAT isozyme bands, L-C1 and L-C2, were detected in cucumber seedling leaves. The L-C1 and

L-C2 band was induced and inhibited by NaCl stress, respectively, and application of exogenous SPD increased their expression. In cucumber seedling roots, R-C1 and R-C2 were visualized on native PAGE gels (Fig. 3B). The isozyme bands were inhibited by salt stress, and exogenous SPD application increased slightly the R-C2 band and did not change the expression of R-C1.

Discussion and Conclusions

Growth analysis is a widely used analytical tool for characterizing plant growth. Of the parameters typically calculated, the most important is relative growth rate. In our study, RGR decreased significantly in cucumber seedlings exposed for 3 d to 50 mM NaCl, and plant growth was suppressed compared with the control (Table 1). The third leaf area did not significantly change due to salt stress because the leaf was almost fully expanded from the beginning of treatment. Exogenous SPD sprayed on cucumber leaves alleviated short-term salinity-mediated growth reduction by varying degrees.

Our results showed that salt stress significantly increased free radical production and MDA content in cucumber seedling leaves and roots (Table 2). Exogenous SPD reversed the increase, which was greater in roots than in leaves. The effect of SPD sprayed on leaves on free radical production and MDA content in cucumber seedlings was similar to the effect of SPD application to roots via nutrient solution described by Duan et al. (2008). LOX is ubiquitous in plants and catalyzes dioxygenation of the plant fatty acids, linoleic and linolenic acids, has deleterious effects on membranes and proteins (Todd et al., 1990). In our study, however, salt stress significantly decreased LOX activity in leaves and increased slightly in roots, and LOX activities in leaves and roots were decreased by exogenous SPD. This implicates that it is probable that salt has not activated LOX in cucumber seedlings and that SPD may be associated more with LOX. Further study needs to proceed in our laboratory.

ROS are toxic molecules capable of injuring or even killing plant cells, and their level in cells must be tightly regulated (Mittler et al., 2004; Neill et al., 2002). To prevent ROS, various ROS-scavenging enzymes, including SOD, CAT, and POD, have been observed under salt stress. For example, it has been reported that ROS-scavenging enzymes increased under saline conditions in the shoots of soybean [Glycine max (Ghorbanli et al., 2004)], cucumber (Duan et al., 2008), and chickpea [Cicer arietinum (Kukreja et al., 2005)], but decreased in the roots of wheat [Triticum aestivum (Meneguzzo et al., 1999)] or were unaffected, as in the case of SOD in cucumber (Lechno et al., 1997) and CAT in soybean roots (Ghorbanli et al., 2004). In the present study, NaCl treatment increased the levels of SOD, the enzyme that converts superoxide to H$_2$O$_2$. However, with regard to enzymes that convert H$_2$O$_2$ to water, POD activity increased, whereas CAT decreased in roots. This suggests that POD plays a vital role in H$_2$O$_2$ detoxification under salt stress, but CAT in roots does not. Moreover, the decrease in CAT activity in response to salt stress is a phenomenon that occurs in many plant species (Corpas et al., 1993; Shim et al., 2003; Streub and Feierabend, 1996). In some cases, however, CAT activity increases following NaCl treatment, as observed in rice [Oryza sativa (Lin and Kao, 2000)] and cucumber (Lechno et al., 1997). This indicates that enzyme responses may vary according to the intensity of the stress, plant part, amount of time in which the plant has been stressed, and induction of new isozyme(s).

It is well documented that PAs counteract oxidative damage in plants by acting as direct free radical scavengers (Bors et al., 1989). SPD may act as a protectant for the plasma membrane against stress damage by maintaining membrane integrity (Roy et al., 2005). Moreover, it is probable that SPD acts as a signaling regulator in stress-signaling pathways (Kasukabe et al., 2004). In the present study, the effects of salinity on growth, free radical production, membrane damage, and antioxidant enzymes were modified by exogenous SPD application. Moreover, exogenous SPD significantly reduced salinity-induced increase of O$_2^{-}$ and H$_2$O$_2$, but did not significantly increase ROS-scavenging enzyme activities during salt stress. Thus, it shows that SPD is potentially acting as direct free radical scavenger in cucumber seedlings treated with salinity.

Isozyme analysis has provided us with a relatively simple tool for evaluating gene flow, selection pressure, and genetic relationships (Gottlieb and Weeden, 1981). In isozyme charts, the color of the enzyme bands can reflect the relative quantity of the isozyme activity (Milone et al., 2003). Unlike most other organisms, plants possess multiple enzymatic forms of SOD. Three classes of SOD can be distinguished according to their metal cofactor and subcellular localization: copper/zinc, manganese, and iron forms (Bannister et al., 1987). The abundance of SOD isozymes is highly variable and is regulated by environmental and developmental stimuli (Bowler et al., 1992). In the present study, the majority of the SOD isozymes were induced by NaCl stress, and application of exogenous SPD increased the expression of some isozymes. The changes of these isozymes are consistent with activities, which further shows that SOD plays a protective role against environmental stress by converting superoxide to H$_2$O$_2$. POD possesses a large number of isozymes, and even more genes. Plant PODs are divided into three subgroups based on their pl: anionic, neutral, or cationic. The anionic POD isozymes have been studied most extensively with respect to their expression in response to developmental and environmental factors, including their possible role in plant defense (Huh et al., 1997). However, the available molecular and biochemical details of peroxidase function have not been well clarified in plant development and the stress response (Dalton et al., 1998). In the present
experiment, activities and isozymes of POD were greatly increased in cucumber seedlings 3 d after treatment initiation. Salt stress increased the accumulation of the POD enzyme and the encoding gene was accelerated in response to salt stress. These results are in agreement with the findings of El-Baz et al. (2003) and Sreenivasulu et al. (1999). Application of SPD further induced the activity and expression of POD isozymes. Our results show that POD is one of the key antioxidant enzymes and contributes to protection against salt-induced oxidative stress in cucumber seedlings. Willekens et al. (1995) has proposed a classification for dicot CAT enzymes that relates primary structure with function. Class I is mainly associated with photosynthesis, and Class III with fatty acid degradation in glyoxysomes. Class II may be particularly important for protection against environmental stress. In our study of the ROS-metabolizing enzymes examined, the CAT isozymes in root cells decreased under salinity, consistent with activity. Detailed expression analyses of CAT in several plant species have clearly demonstrated that CAT isozymes are differentially expressed, even when the stress condition and accumulate in different tissues of the plant (Willekens et al., 1995). The differential expression of CAT strongly suggests that each CAT isozyme has a specific cellular function.

In conclusion, short-term salt stress caused a clear suppression of plant growth. This inhibition could be reversed via exogenous application of SPD by spraying leaves. These experiments demonstrate that the altered expression of three antioxidant enzymes has a dramatic effect on the physiology and morphology of the plant. However, under induction treatment of the ROS-scavenging enzymes examined, changes in CAT enzymes are inconsistent with SOD and POD. By altering the expression of isozymes in metabolic pathways, it should be possible not only to delineate which isozyme is important, but also to determine the influence of salt stress on the antioxidant enzymes. These interactions are very complex and are related to the plant treatment time, tissues, species, and genotypes. Exogenous SPD greatly promoted the activity and expression of POD and SOD and alleviated the oxidative stress induced by salt stress in cucumber seedlings. Therefore, the protective role of SPD may be attributed to its ability to mediate the expression of genes encoding these ROS-scavenging enzymes under short-term salt stress.
