We present a microscopic theory of magnon transport in ferromagnetic insulators (FIs). Using magnon injection through microwave pumping, we propose a way to generate magnon dc currents and show how to enhance their amplitudes in hybrid ferromagnetic insulating junctions. To this end focusing on a single FI, we first revisit microwave pumping at finite (room) temperature from the microscopic viewpoint of magnon injection. Next, we apply it to two kinds of hybrid ferromagnetic insulating junctions. The first is the junction between a quasi-equilibrium magnon condensate and magnons being pumped by microwave, while the second is the junction between such pumped magnons and noncondensed magnons. We show that quasi-equilibrium magnon condensates generate ac and dc magnon currents, while noncondensed magnons produce essentially a dc magnon current. The ferromagnetic resonance (FMR) drastically increases the density of the pumped magnons and enhances such magnon currents. Lastly, using microwave pumping in a single FI, we discuss the possibility that a magnon current through an Aharonov-Casher phase flows persistently even at finite temperature. We show that such a magnon current arises even at finite temperature in the presence of magnon-magnon interactions. Due to FMR, its amplitude becomes much larger than the condensed magnon current.

I. INTRODUCTION

Since the observation of spin-wave spin currents in Y₃Fe₅O₁₂ (YIG), ferromagnetic insulators (FIs) have been playing a major role in spintronics. The main advantages of magnons in FIs can be summarized in the following points: First, transport of magnons in insulating magnets has a lower power absorption compared to electronic conductors. Next, it has been shown experimentally by Kajiwara et al. that magnon currents can carry spin-information over distances of several millimeters, much further than what is typically possible when using spin-polarized conduction electrons in magnetic metals. Third, magnons are quasi-particles (i.e., magnetic excitations) which are not conserved. Using microwave pumping, they can be directly injected to FIs and their density controlled. A further advantage of magnons arises from the feature that magnons are bosonic excitations and as such they can form a macroscopic coherent Bose-Einstein condensate (BEC). Demokritov et al. have indeed experimentally shown that such a magnon-BEC can be generated even at room temperature in YIG by using microwave pumping, and Serga et al. have recently addressed the relation between microwave pumping and the resulting magnon-BEC (Fig. 1); the applied microwave drives the system into a nonequilibrium steady state and continues to populate the zero-mode of magnons and thereby reaches a quasi-equilibrium state where the pumped magnons form a quasi-equilibrium magnon-BEC. The thermalization period is about 50ns, while the decay time of quasi-equilibrium magnon-BECs amounts to 400ns and they can survive for 1μs.

FIG. 1: (Color online) A schema of the time-evolution of the quasi-equilibrium magnon-BEC density due to microwave pumping where (i) microwave pumping, (ii) thermalization (or relaxation) process, and (iii) quasi-equilibrium magnon-BEC state. This schematic picture is based on the experiment by Serga et al. of Ref. 5. The applied microwave drives the system into a nonequilibrium steady state and continues to excite the zero-mode of magnons (i.e., pumped magnons). After microwave is switched off, the system experiences a thermalization process for a short time, and immediately reach a quasi-equilibrium state where the pumped magnons can form a quasi-equilibrium magnon-BEC. The thermalization period is about 50ns, while the decay time of quasi-equilibrium magnon-BECs amounts to 400ns and they can survive for 1μs.
herent precession in terms of spin variables which can last for about 1\(\mu\)s.

Motivated by these experimental progress, we microscopically analyzed in Ref. [4] the transport properties in such realized quasi-equilibrium magnon-BECs in FI junctions, and discussed the ac and dc Josephson effects through the Aharonov-Casher (A-C) phase\(^{23}\), being a special case of a Berry phase\(^{4,5,15}\) in this system. We found that this A-C phase gives a handle to electromagnetically control the Josephson effects and to realize a persistent magnon-BEC current\(^{17,24,25}\) in a ring. An experimental proposal to directly measure this magnon-BEC current also has been theoretically proposed in Ref. [7] through measurements of the induced electric field.

Toward the direct measurement of such magnon currents, one concern might be, however, that the amount of the magnon currents and the resulting electric fields (of the order of \(\mu\)V/m) is still very small. This might be an obstacle to the feasibility of such experiments at present.

To overcome this problem, we propose to use instead magnon injection through microwave pumping\(^{4,5,15}\) which offers an alternative method to enhance magnon currents in FIs. Because the density of noncondensed magnons is still much larger than that of the magnon condensates in realistic experiments, we consider two kinds of hybrid FI junctions. The first one (Fig. 2) is a junction between quasi-equilibrium magnon condensate and magnons being pumped by microwaves, while the second one (Fig. 5) is a junction between pumped magnons and noncondensed magnons. In order to lighten notations, we denote them as the C-P (Fig. 2) and NC-P (Fig. 5) junctions, with ‘C’ for quasi-equilibrium magnon condensates, ‘P’ for pumped magnons, and ‘NC’ for noncondensed magnons.

This paper is organized as follows. In Sec. II we first focus on a single FI (P) and microscopically revisit microwave pumping\(^{4,5,15}\) at finite (room) temperature from the viewpoint of magnon injection. In Sec. III we apply these ideas to C-P and NC-P junctions and show that dc magnon currents can arise from an applied ac magnetic field (i.e., microwaves). The amount is drastically enhanced by the ferromagnetic resonance (FMR). We also address the distinctions between the C-P, NC-P, and C-C junctions. Lastly in Sec. IV using a magnon current through the A-C phase, we point out the possibility that such realized magnon currents flow persistently even at finite temperature due to microwave pumping. The predicted amount turns out to be much larger, about \(10^3\) times, than the magnon-BEC current predicted in Ref. [7]. Finally, Sec. V summarizes our results.

II. C-P JUNCTION

We consider the C-P junction shown in Fig. 2 between two FIs, the left FI (C) being in a quasi-equilibrium magnon-BEC\(^{4,5}\), while magnons are being pumped into the right FI (P) by the applied microwave field\(^{12}\). We assume that the magnons in the left FI have already reached a quasi-equilibrium condensate state (i.e., after microwave pumping) through a procedure such as realized in Ref. [4], while we continue to apply a microwave only to the right FI and generate continuously magnons.

FIG. 2: (Color online) Schematic representations of a C-P junction between two FIs, one prepared as BEC (left FI) and the other (right FI) with pumped magnons. (a) Both magnetic fields are applied along the \(z\)-axis, \(B_{L(R)} = B_{L(R)}e_z\). The circles in the right FI are the magnons pumped by microwaves (frequency \(\Omega \sim 100\text{MHz}\)) and the cloud of circles in the BEC represents the quasi-equilibrium magnon condensate. Both phases correspond to a macroscopic coherent precession in terms of spin variables \(S_{L(R)}\) and \(S_{R}\). A distinct difference, however, is that the frequency of the magnon-BEC is controlled by the applied magnetic field \(B_L (\sim \text{mT})\), while that of the pumped magnons by the frequency \(\Omega\) of the applied microwave. The relation between \(g\mu_B B_L / \hbar\) and \(\Omega\) plays the key role in the ac-dc conversion of magnon currents. Tuning \(\hbar\Omega = g\mu_B B_L\), a FMR occurs in the right FI and consequently, the number of pumped magnons drastically increases. (b) Close-up of the C-P junction. Only the boundary spins \(S_{FL}\) in the left FI and \(S_{FR}\) in the right FI are relevant to magnon transport. We assume a large spin \(S \gg 1\). The two FIs are separated by an interface and thereby weakly exchange-coupled with strength \(J_{xx}\). For typical values \(J_{xx} \sim 0.1\mu\text{eV}\) this gives rise to an interface of width \(\sim 10\text{Å}\).
A. Spin Hamiltonian

Each three-dimensional FI depicted in Fig. 2 is described by a Heisenberg spin Hamiltonian in the presence of a Zeeman term (we assume a cubic lattice),

\[ H_{\text{FI}} = -J \sum_{\langle ij \rangle} S_i \cdot S_j - g \mu_B B_{\text{L(R)}} \cdot S_i, \]

where \( S_i \) denotes the spin of length \( S \) at lattice site \( i \), \( J > 0 \) represents the isotropic exchange interaction, and \( B_{\text{L(R)}} = B_{\text{L(R)}} \hat{e}_z \) is an applied magnetic field to the left (right) FI (\( \hat{e}_z \) denotes the unit vector along the z-axis). The symbol \( \langle ij \rangle \) indicates summation over neighboring spins in each FI. We then use the Holstein-Primakoff transformation

\[ S_i^+ = \sqrt{2S} \left[ 1 - a_i^\dagger (2S)^{1/2} a_i \right] \]

and \( S_i^- = S - a_i^\dagger a_i \), and map Eq. (1) onto a system of magnons that satisfy \( [a_i, a_j^\dagger] = \delta_{i,j} \). The long wave-length approximation gives the energy dispersion relation of magnons \( \omega_k = 2JSa_i^2k^2 + g \mu_B B_{\text{L(R)}} = Dk^2 + g \mu_B B_{\text{L(R)}} \), where \( a \) denotes the lattice constant, \( |k| = k \), and \( D = 2JSa_i^2 \). Since we consider the exchange interaction \( J \) to be isotropic and and assume a large \( S \), the magnon-magnon interactions (i.e., nonlinear effects) that could arise as the \( \mathcal{O}(S^0) \)-term do not influence the transport of magnons between such FIs in any significant manner and we can neglect them in that case (see also Sec. [11][12]). The microscopic relation between the spin Hamiltonian \( H_{\text{FI}} \) [Eq. (1)] and the Gross-Pitaevskii (GP) Hamiltonian that describes the Josephson effect in magnon-BECs has been addressed in Ref. [7]. We here stress that the isotropic spin Hamiltonian \( H_{\text{FI}} \) corresponds to the case \( \eta = 1 \) of the GP Hamiltonian. Therefore, the GP Hamiltonian actually shows that the magnon-magnon interactions do not influence transport of condensed magnons in such C-P junctions.

Due to a finite overlap of the wave functions, there exists in general a finite exchange interaction between the spins located at the boundaries of the different FIs. Thus, only the boundary spins, denoted as \( S_{R_L} \) and \( S_{L_R} \) in the left and right FI, respectively (see Fig. 2), are relevant to transport of magnons in the junction. The exchange interaction between the two FIs may thus be described by the Hamiltonian

\[ H_{\text{ex}} = -J_{\text{ex}} \sum_{\langle \Gamma_L \Gamma_R \rangle} S_{\Gamma_L} \cdot S_{\Gamma_R}, \]

where \( J_{\text{ex}} > 0 \) is the magnitude of the exchange interaction at the interface. The two FIs are assumed to be weakly exchange-coupled, i.e., \( J_{\text{ex}} \ll J \). In terms of magnon operators, \( H_{\text{ex}} \) can be rewritten as

\[ H_{\text{ex}} = -J_{\text{ex}} S \sum_{\langle \Gamma_L \Gamma_R \rangle} \left( a_{\Gamma_L} a_{\Gamma_R}^\dagger + a_{\Gamma_R}^\dagger a_{\Gamma_L} \right) + \mathcal{O}(S^0). \]

We have ignored terms arising from the z-component of the spin variables in the Hamiltonian \( H_{\text{ex}} \), since these do not influence the dynamics of the junction.

Finally, the total Hamiltonian \( \mathcal{H} \) that describes transport of magnons in the junction reads

\[ \mathcal{H} = H_{\text{FI}} + H_{\text{ex}}. \]

Using the Heisenberg equation of motion, the time-evolution under \( \mathcal{H} \) of the magnon density operator \( I \) in the left FI becomes

\[ i \hbar \partial_t n_L(t) = -i J_{\text{ex}} S a_L(t) a_R^\dagger(t) / \hbar + \mathcal{H}_\text{c.c.}, \]

where \( n_L(t) \equiv a_L^\dagger(t) a_L(t) \) is the operator of the magnon number density. The operator \( I \) characterizes the exchange of spin angular momentum via magnons per unit time between the FIs. Therefore (in that sense) it could be regarded as the magnon current density operator in the FI junction.

B. Microwave pumping

To clarify the features of transport of magnons in the C-P junction, we first focus on the right FI (the pumped magnon part of the C-P junction) and microscopically revisit microwave pumping \[13,15,33,34] from the viewpoint of magnon injection \[4\] (Fig. 1). The interaction between the spins in the FI (P) and the applied microwave (i.e., clockwise rotating magnetic field) may be described by the Hamiltonian

\[ V_{ac} = -g \mu_B \Gamma_0 \sum_j \left[ e^{i(\Omega t + \vartheta_{ac})} S_j^+ + e^{-i(\Omega t + \vartheta_{ac})} S_j^- \right] \]

\[ + \mathcal{O}(S^{-1/2}). \]

1. FMR

Using again the Heisenberg equation of motion, the time-evolution of the magnon density \( n_R(t) \equiv a_R^\dagger(t) a_R(t) \) under microwave pumping [i.e. \( V_{ac} \) in Eq. (6)] becomes

\[ \langle \dot{n}_R(t) \rangle_P = -i \frac{\sqrt{2S} g \mu_B \Gamma_0}{\hbar} \langle a_R(t) \rangle_P e^{i(\Omega t + \vartheta_{ac})} + \mathcal{O}(\Gamma_0^3), \]

which shows that \( \dot{S} = S/\alpha^3 \). The subscript ‘P’ in \( \langle a_R(t) \rangle_P \) means the expectation value under microwave pumping \( V_{ac} \). Treating \( V_{ac} \) as the perturbative term, the standard procedure \[37] of the Schwinger-Keldysh formalism \[38,39] gives

\[ \langle a_R(t) \rangle_P = i \sqrt{2S} g \mu_B \Gamma_0 \int_0^t \int_0^t d\tau' \int_0^\infty dr' \]

\[ \times \left( T_e a_R(\tau) a_R^\dagger(\tau') \right) e^{-i(\Omega t + \vartheta_{ac}) / \hbar} + \mathcal{O}(\Gamma_0^3), \]

where \( T_e \) is the time-reversal operator.
where \( \tau \) and \( \tau' \) denote the contour variables defined on the Schwinger-Keldysh closed time path, and \( T_c \) is the path-ordering operator defined on it. Using the Langreth method, it becomes

\[
\langle a_R(t) \rangle_p = -\sqrt{2S}g_\mu B_0 \int dt' \int dt' \frac{1}{\hbar} e^{-i(\Omega t + \sigma_{ac})/\hbar},
\]

where \( G^{t}(t, t') \equiv G^{t}(t, t') \) is the bosonic time-ordered (lesser, retarded) Green function, which satisfies \( G^{r} = G^{t} - G^{c} \). After Fourier transformation, it becomes

\[
\langle a_R(t) \rangle_p = -\sqrt{2S}g_\mu B_0 \int dt' e^{-i(\Omega t + \sigma_{ac})/\hbar}. \tag{8}
\]

Phenomenologically introducing a finite life-time \( \tau_p \) (\( \sim 100 \text{ns} \)) of the pumped magnons mainly due to non-magnetic impurity scatterings, it becomes

\[
\langle a_R(t) \rangle_p = \frac{-\sqrt{2S}g_\mu B_0}{\hbar \Omega - g_\mu B R} e^{-i(\Omega t + \sigma_{ac})}. \tag{9}
\]

The zero-mode population of magnons is generated by microwave pumping [Eq. (9)] and the number density of the pumped magnons \( \langle n_R \rangle_p = \langle a_R(t) \rangle_p a_R(t) \) reads

\[
\langle n_R \rangle_p = \frac{2S g_\mu B_0^2}{(\hbar \Omega - g_\mu B R)^2 + \left( \frac{\hbar}{2 \tau_p} \right)^2}. \tag{10}
\]

In terms of spin variables, Eq. (10) shows a homogeneous macroscopic coherent precession with the frequency \( \Omega \) which can be semiclassically treated. The applied microwave forces spins to precess coherently at the same frequency \( \Omega \) with the microwave. Thus, we can control the frequency of the homogeneous coherent precession through the applied microwave field.

Eq. (10) shows that the number density of pumped magnons strongly increases at the FMR (Fig. 3)

\[
\hbar \Omega = g_\mu B R. \tag{12}
\]

With the help of Eqs. (7) and (10), the resulting magnon pumping rate becomes

\[
\langle \dot{n}_R \rangle_p = 8\tau_p S g_\mu B_0^2/\hbar. \tag{13}
\]

Assuming \( \Gamma_0 = 0.25 mT \), \( \tau_p = 100 \text{ns} \), \( \alpha \approx 1 \text{A} \), \( g = 2 \), and \( S = 16 \), the magnon pumping rate amounts to \( \langle \dot{n}_R \rangle_p \approx 10^{26} \text{cm}^{-3} \text{s}^{-1} \) at FMR. Thus, using microwave pumping, we can continuously inject zero-mode magnons into the right FI (P).

2. Magnon-magnon interaction

We next consider the finite (room) temperature effect on microwave pumping. We remark that a theory\cite{35,36,37,38,39} on microwave pumping at zero-temperature has been considered before, but to the best of our knowledge not yet for finite temperatures.

Assuming an anisotropic exchange interaction among the nearest neighboring spins, in addition to \( V_{ac} = O(S^{1/2}) \) [Eq. (6)], magnon-magnon interactions \( H_{FI}^{m-m} \) may arise\cite{7,35} from the anisotropic Heisenberg spin Hamiltonian. By keeping the \( O(S^0) \)-term, we obtain

\[
H_{FI}^{m-m} = -J_{m-m} \sum_{(ij)} a_i^\dagger a_j^\dagger a_i a_j. \tag{14}
\]

The magnitude and the sign of the magnon-magnon interaction \( J_{m-m} \) depend on the anisotropy of the exchange interaction among the nearest neighboring spins in the right FI, and we assume

\[
| J_{m-m} | \ll J,
\]

to be treated perturbatively (i.e., a small anisotropy). Taking this magnon-magnon interaction into account, we evaluate the expectation value \( \langle a_R(t) \rangle_p^{m-m} \) and clarify the finite temperature effect on microwave pumping.

Following the same procedure with Sec. IIIB, a straightforward calculation\cite{37} based on Schwinger-Keldysh formalism\cite{38,39} gives

\[
\langle a_R(t) \rangle_p^{m-m} = \frac{4i \sqrt{2S} J_{m-m} g_\mu B_0 \hbar \alpha^3}{\hbar^2} \int dt' \int dt'' e^{-i(\Omega t') + \sigma_{ac}}
\]

\[
\times \left[ \int dt' \int dt'' e^{-i(\Omega t'' + \sigma_{ac})} G_R^{<}(t'', t') \right]
\]

\[
\times \left[ G_R^{<}(t, t'') G_R^{>}(t', t'') - G_R^{<}(t, t'') G_R^{>}(t'', t') - G_R^{<}(t, t'') \sigma_R G_R^{>}(t'', t') + \sigma_R G_R^{>}(t', t'') \right]
\]

\[
+ O(J^2_{m-m}).
\]
where \( \mathcal{G}(\mathbf{r}, t, t') = \mathcal{G}(t, t') \) and \( \mathcal{G}^{(i, <, >)} \) is the bosonic time-ordered (anti-time ordered, lesser, greater) Green function. Using the retarded (advanced) Green function \( \mathcal{G}^{(i)} \), they satisfy
\[
\mathcal{G}^{(i)} = \mathcal{G} + \mathcal{G}^{<} = \mathcal{G}^{<} - \mathcal{G}^{i},
\]
and \( \mathcal{G}^{<} - \mathcal{G}^{>} = \mathcal{G}^{a} - \mathcal{G}^{r}. \) Consequently, after the Fourier transformation, it becomes
\[
\langle a_R(t) \rangle_{P}^{m-m} = 4\sqrt{2J}m \mu_B \Gamma_0 \alpha^3 \left[ \sum_k f_B(\omega_k^R) / V \right] \times \left( \mathcal{G}^R_{k, k=0, \Omega} \right)^2 e^{-i(\Omega t + \theta_{ac})},
\]
(15)
where \( f_B(\omega_k^R) = (e^{\omega_k^R} - 1)^{-1} \) is the Bose-distribution function, \( \beta = 1/(k_B T) \) the inverse temperature, and \( V \) the volume of the system (here the right FI). We now assume room temperature \( T \approx 300K \), which implies \( f_B(\omega_k^R) \approx k_B T / \omega_k^R \). Using this approximation, Eq. (15) becomes
\[
\langle a_R(t) \rangle_{P}^{m-m} \approx 4\sqrt{2J}m \mu_B \Gamma_0 \alpha^3 k_B T \left( \hbar \Omega - \mu_B B_R + \frac{\hbar \Omega}{2 \tau_p} \right)^2 e^{-i(\Omega t + \theta_{ac})},
\]
(16)
where the constant \( \gamma \) is defined by \( \sum_k f_B(\omega_k^R) / V \equiv \gamma k_B T \). Assuming \( J = 0.1eV, B_R = 50mT, \alpha \approx 1 \AA, g = 2, \) and \( \Omega = 16, \tau_p = 100ns, \Gamma_0 = 0.5\mu T, \) it amounts to \( \gamma \alpha^3 \approx 5 \times 10^{-4} eV^{-1} \).

Eq. (16) shows that even in the presence of the magnon-magnon interaction \( J_{m-m} \), the temperature dependence of pumped magnons at high temperatures becomes [Eqs. (11) and (13)]
\[
\langle n_R \rangle_T + \langle n_R \rangle_{P}^{m-m},
\]
where \( \langle n_R \rangle_T = \mathcal{O}(J_{m-m}^2) \) and \( \langle n_R \rangle_{P}^{m-m} = \mathcal{O}(J_{m-m}^2) \). The amount of such pumped magnons becomes maximally at the FMR \( (h \Omega = \mu_B B_R) \) and it increases with increasing temperature. Assuming \( S = 16, g = 2, \) \( \tau_p = 100ns, \Gamma_0 = 0.5\mu T, \gamma \alpha^3 \approx 5 \times 10^{-4} eV^{-1}, T = 300K, \) and \( J_{m-m} = 25\mu eV, \) we get from Eqs. (11) and (13) \( \langle n_R \rangle_T \sim 1 \times 10^{22} cm^{-3} \) and \( \langle n_R \rangle_{P}^{m-m} \sim 2 \times 10^{21} cm^{-3} \) at the FMR.

C. Nonequilibrium magnon currents

Next, we apply the results obtained in Sec. [13] to the hybrid C-P junction (Fig. 1); the junction between the magnon-BEC in the left FI (C) and the pumped magnons in the right FI (P). Assuming again isotropic exchange interaction \( \mathcal{H}_{EF} \) [Eq. (1) among the nearest neighboring spins whose spin length are large enough [33,34] [i.e. \( S = \mathcal{O}(10^4) \)], we continue to apply microwave only to the right FI (P) and clarify the features of magnon transport. We remark that in terms of spin variables, both correspond to a macroscopic coherent precession. A distinct difference, however, is that the frequency of quasi-equilibrium magnon-BECs is essentially characterized by the applied magnetic field \( B_L \) in the left FI (C), while that of pumped magnons by the frequency \( \Omega \) of the applied microwave [Eq. (10)]. This plays the key role in the ac-dc conversion of the magnon current we describe below. The number of magnons in the C-P junction is not conserved due to the magnon injection through microwave pumping. Therefore the Josephson equation of the C-C junction microscopically derived in Ref. [7] is not directly applicable to the C-P junction.

Since both the quasi-equilibrium magnon condensate and the pumped magnons correspond to macroscopic coherent precession in terms of spin variables, they may be treated semiclassically. Therefore, following Ref. [8] the interaction between them may be described by the Hamiltonian [Eq. (3)]
\[
\mathcal{H}_{ex}^{C-P} = -J_{ex} S \sum_{(\Gamma, \Gamma a)} \left[ \langle a_{\Gamma a} \rangle_C (a_{\Gamma a}^\dagger)_P + c.c. \right],
\]
(20)
where \( \langle a_{\Gamma a} \rangle_C \) is the expectation value in the quasi-equilibrium magnon-BEC state. Under the Hamiltonian \( \mathcal{H}_{ex}^{C-P} \), a nonequilibrium magnon current arises from microwave pumping in the C-P junction [Eq. (14)],
\[
\langle I(t) \rangle_{C-P} = -iJ_{ex} S \langle a_{\Gamma a} \rangle_C (a_{\Gamma a}^\dagger)_P / \hbar + c.c.,
\]
(21)
where \( \langle a_{\Gamma a} \rangle_C = \sqrt{n_{\Gamma a}(t)} \text{exp}[-i\theta_{\Gamma a}(t)]. \) The magnon number density in the left FI is \( n_{\Gamma a}(t) \) and the phase
The magnon current density becomes \( \partial_t \langle I(t) \rangle_{C,P} \) in the C-P junction. They are characterized by the GP Hamiltonian that can be microscopically derived from the spin Hamiltonian \( \mathcal{H}_S \) (see Eq. (11) in Ref. [7]). The GP Hamiltonian actually shows that only the homogeneous condensates play a role, without space dependence of \( \langle a_i(t) \rangle_C \). Associated with the macroscopic coherence, the magnon current \( \langle I(t) \rangle_{C,P} \) arises from the \( \mathcal{O}(J_{\text{ex}}) \)-term. This is the same with the Josephson magnon current in BECs addressed in Ref. [7].

We further remark that there could be some contributions in Eq. (21) [or Eq. (3)] that might arise from higher order terms in the Holstein-Primakoff expansion\(^{32}\) [e.g. \( \mathcal{O}(S^0) \) and \( \mathcal{O}(S^{-1}) \)]. Such contributions can be taken into account by using the semiclassical relation \( \langle S^+ \rangle_{C,P} = \sqrt{2S} [1 - \langle a_i \rangle_{C,P} \langle a_i \rangle_{C,P}^\dagger] / (2S)^{1/2} \langle a_i \rangle_{C,P} \). We have actually confirmed [Eq. (10)] that the main mechanism responsible for the magnon currents remains in place even in the presence of such higher order terms. In addition, we now assume a large spin\(^{4,33,34}\) \( S \approx 10 \). Therefore, this is enough to focus on the magnon current \( \langle I \rangle_{C,P} = \mathcal{O}(S) \) expressed by Eq. (21).

Using Eqs. (10) and (12), the term \( \langle a_R(t) \rangle_P \) in Eq. (21) on FMR reads

\[
\langle a_R(t) \rangle_P = \frac{2i t \tau_P}{\hbar} \sqrt{2 S} g \mu_B \Gamma_0 e^{-i(\Omega t + \theta_{ac})}.
\]

Consequently, the magnon current density [Eq. (21)] becomes

\[
\langle I \rangle_{C,P} = -\frac{4 \tau_P J_{\text{ex}} S \sqrt{2S} n L g \mu_B \Gamma_0}{\hbar^2} \times \cos(\theta_L(t) - \Omega t + \theta_{ac}).
\]

This is the general expression of the magnon current density in the C-P junction.

We recall that the frequency of the coherent precession due to the magnon-BEC \( \dot{\theta}_L(t) \) can be essentially characterized by the effective magnetic field along the z-axis\(^{33}\) and the magnitude can be controlled by the applied magnetic field,

\[
\dot{\theta}_L(t) = \frac{g \mu_B B_L}{\hbar}.
\]

Thus, by tuning it to the microwave frequency (Fig. 2)

\[
g \mu_B B_L / \hbar = \Omega,
\]

the magnon current density becomes

\[
\langle I \rangle_{C,P} = -\frac{4 \tau_P J_{\text{ex}} S \sqrt{2S} n L g \mu_B \Gamma_0}{\hbar^2} \times \cos(\theta_L(0) - \theta_{ac}).
\]

This result proves that by adjusting the frequency of the applied microwave in the right FI to that of the magnon-BEC in the left FI, a dc magnon current can arise from an applied ac magnetic field [Fig. 1(a)].

We note that the dc magnon current arises not from the FMR condition given in Eq. (12) (see Fig. 3), \( g \mu_B B_R = \hbar \Omega \), but from the condition between magnon-BECs and microwaves [Eq. (25) and Fig. 1(a)], \( g \mu_B B_L = \hbar \Omega \). That is, if only the frequency of the applied microwave in the right FI is adjusted to that of the magnon-BEC in the left FI [Eq. (25)], a dc magnon current can arise. The condition for FMR [Eq. (12)] is not responsible for the ac-dc conversion of the magnon current but it does lead to its drastic enhancement, see Fig. 3.

Assuming\(^{4,33,34}\) \( J_{\text{ex}} \approx 0.1 \mu \text{eV} \), \( \Gamma_0 = 0.125 \mu \text{T} \), \( \tau_P = 100 \text{ns} \), \( \alpha \approx 1 \text{A} \), \( \dot{\theta}_L(0) - \theta_{ac} \approx 0 \), and\(^{20}\) \( n_L \sim 10^{19} \text{cm}^{-3} \), the magnitude of the dc magnon current [Eq. (26)] becomes \( | \langle I \rangle_{C,P} | \sim 10^{29} \text{cm}^{-3} \text{s}^{-1} \). Due to the magnon injection through microwave pumping and the resulting FMR, it is worth stressing that this value is actually much larger, about \( 10^6 \) times, than the one obtained from the dc Josephson magnon current in the C-C junction (the ‘C-C’ junction denotes the FI junction between magnon condensates (C) that was introduced in Ref. [7]).

The magnon currents can be experimentally measured by using the same method\(^{2,9,10}\) as for the Josephson magnon current described in Ref. [7]. Since the moving magnetic dipoles (i.e., magnons with magnetic moment \( g \mu_B \mathbf{e}_z \)) produce electric fields, magnon currents can be observed by measuring the resulting voltage drop, \( \Delta V \), which is proportional to the amount of the magnon current. This means that the voltage drop in the C-P junction becomes much larger, about \( 10^6 \) times, than the one in the C-C junction. Therefore we expect that the measurement of the magnon currents in the C-P junction is experimentally better accessible than the Josephson magnon currents in the C-C junction. We remark that applying an electric field to the interface and using the

\[ \Delta V = \text{Constant} \times N_L \text{ at } \langle I \rangle_{C,P} \]

FIG. 4: Plots of the rescaled magnon number \( N_L \equiv n_L \alpha^3 \) as function of the rescaled time \( T \equiv (J_{\text{ex}} S / \hbar) t \) obtained by numerically solving Eq. (27) for the values \( g = 2 \), \( S = 16 \), \( J_{\text{ex}} \approx 0.1 \mu \text{eV} \), \( \Gamma_0 = 0.125 \mu \text{T} \), \( \tau_P = 100 \text{ns} \), \( \alpha \approx 1 \text{A} \), \( \dot{\theta}_L(0) - \theta_{ac} = \pi \), \( N_L(T = 0) = 10^{-5} \), and \( \Omega = 400 \text{MHz} \). The rescaled time \( T = 1 \) corresponds to \( t = 5 \text{ns} \) and \( N_L = 10^{24} \text{cm}^{-3} \). \( dN_L / (dT) \) represents the magnon current. (a) \( h \Omega = g \mu_B B_L \) (i.e. \( B_L = 2 \mu \text{mT} \)). This gives the ac magnon current whose period becomes of the order of \( 10^{-1} \mu \text{s} \).
resulting A-C phase as in Ref. 7, we could tune the magnitude of the phase in the cosine function of Eq. (26) and consequently, we might control the direction of the dc magnon current.

D. Distinction from C-C junction

Introducing the rescaled time $T$ and the number of magnons $N_L$ by $t \equiv \hbar T/(J_{\text{ex}}S)$ and $n_L \equiv N_L/\alpha^3$, Eq. (23) can be rewritten as [with the help of Eqs. (24) and (20)]

$$\frac{dN_L(T)}{dT} = -\frac{4\sqrt{2}\tau_p g\mu_B \Gamma_0}{\hbar} \sqrt{N_L(T)}$$

\[\times \cos \left[ \frac{g\mu_B B_L - h\Omega}{J_{\text{ex}}S} T + \vartheta_L(0) - \vartheta_{\text{ac}} \right].$$

Fig. 4 shows the results obtained by numerically solving Eq. (27). Based on them, we summarize the qualitative distinction between the magnon currents in the C-P junction and those in the C-C junction.

1. dc magnon currents

The frequency of the macroscopic coherent spin precession of magnon-BECs is characterized by the magnetic field along the $z$-axis. Through a Berry phase$^{24,25}$ referred to as A-C phase$^{23}$ the dc Josephson magnon current in the C-C junction arises from an applied time-dependent magnetic field (for details, see Ref. 7). In that case, the magnetic field gradient has to be proportional to the time,

$$B_L - B_R \propto t \quad (i.e., B_L \neq B_R). \quad (28)$$

This is the condition for the dc Josephson magnon current in the C-C junction.

On the other hand, the C-P junction does not require such conditions. The applied microwave forces spins to precess coherently [Eq. (10)]. The frequency of the macroscopic coherent precession in the FI (P) is characterized not by the magnetic field $g\mu_B B_r/h$, but by the applied microwave $\Omega$. Therefore by tuning $\Omega = g\mu_B B_r/h$, a dc magnon current can arise [Fig. 1 (a)]. The relation between each magnetic field $B_L$ and $B_R$ has nothing to do with the dc magnon current, which is in sharp contrast to the C-C junction [Eq. (28)].

We note that by adjusting the magnetic field of the right FI (P), $g\mu_B B_R/h = \Omega (= g\mu_B B_l/h)$, FMR does occur and consequently, the pumped magnon drastically increases (Fig. 3). This leads to a drastic enhancement of the dc magnon current. In conclusion, through FMR, a dc magnon current of the C-P junction can arise from the condition [Fig. 1 (a)], $B_L = B_R = \hbar \Omega/(g\mu_B)$, which is in sharp contrast to the C-C junction [Eq. (28)].

2. ac magnon currents

The above discussion is applicable also to the distinction between the ac magnon current in the C-C junction and that in the C-P junction. In the C-C junction, an ac Josephson magnon current arises when a static magnetic field gradient is produced ($B_L(0) = 0$) $B_L - B_R = (\text{constant}) \neq 0$. On the other hand, this condition does not necessarily manifest the ac magnon current in the C-P junction. Even in that case, a dc magnon current arises (due to the same reason explained above) if $B_L = h\Omega/(g\mu_B)$.

Fig. 4 (b) is an example of the ac magnon current in the C-P junction obtained by numerically solving Eq. (27). Assuming $g = 2$, $\Omega = 400$ MHz, and $B_L = 2.05$ mT [i.e., $B_L \neq h\Omega/(g\mu_B)$], the period of the oscillation becomes of the order of $10^{-1}$ ms, which is within experimental reach. The period can be controlled by tuning $\Omega$ or $g\mu_B B_L/h$.

III. NC-P JUNCTION

In the last section (Sec. II), we have seen that quasi-equilibrium magnon condensate generates ac and dc magnon currents from the applied ac magnetic field (i.e., microwave). Microwave pumping and the resulting FMR (Fig. 3) drastically enhance the amount of such magnon currents.

In this section, we further develop it by taking experimental results into account that the density of non-condensed magnons is still much larger than that of the magnon condensate, and thus propose an alternative way to generate a dc magnon current and enhance it.

To this end, we replace the magnon-BECs of the C-P junction (Fig. 2) with noncondensed magnons ($\langle a_L \rangle = 0$) as shown in Fig. 5. Thus we newly consider the hybrid ferromagnetic insulating junction between noncondensed magnons and pumped magnons, namely, the NC-P junction (Fig. 5). The only difference to the C-P junction (Sec. II) is that the magnons in the left FI are not condensed ($\langle a_L \rangle = 0$).

Then, using the microscopic description of microwave pumping addressed in Sec. II B, we clarify the features of the magnon current in the NC-P junction (Fig. 6). Focusing on the effect of the noncondensed magnons on the ac/dc conversion of the magnon current, we then discuss the difference from the C-P and C-C junctions.

A. dc magnon current

Following the same procedure with Sec. II B, a straight-forward calculation based on the Schwinger-Keldysh formalism gives the magnon current $\langle I \rangle_{\text{NC-P}}$ on FMR ($h\Omega = g\mu_B B_R$) in the NC-P junction

$$\langle I \rangle_{\text{NC-P}} = 2\Re \left[ \frac{i}{h} \langle J_{\text{ex}}S \tau_p \sqrt{2S g\mu_B \Gamma_0} \rangle^2 \varphi_{L,k=0,\Omega}^* \right], \quad (29)$$

$$B_L - B_R \propto t \quad (i.e., B_L \neq B_R). \quad (28)$$

This is the condition for the dc Josephson magnon current in the C-C junction.
FIG. 5: (Color online) Schematic representation of the NC-P junction, consisting of a left FI with noncondensed magnons (NC) and a weakly exchange coupled right FI with pumped magnons (P). The microwave at frequency \( \Omega \) is applied only to the right FI. The distinction to the C-P junction in Fig. 2 is that the magnons in the left FI are not condensed (i.e., \( \langle a_L \rangle = 0 \)). Due to the exchange interaction \( H_{ex} \) [Eq. (4)], the applied microwave to the right FI can indirectly affect the noncondensed magnons of the left FI and thereby generate an indirect FMR there.

where \( G^r \) is the bosonic retarded Green function. We then phenomenologically introduce a life-time \( \tau_{NC} \) of noncondensed magnons in the left FI mainly due to non-magnetic impurity scatterings into the Green function \( G^r \) (in the same way with Sec. II B). Consequently, the magnon current density becomes

\[
\langle I \rangle_{NC-P} = \frac{1}{\hbar^2 \tau_{NC}} \left( 2\sqrt{2}S J_{ex} S g \mu_B \Gamma_0 \right)^2 \left( \hbar \Omega - g \mu_B B_L \right)^2 + \left[ \hbar / (2\tau_{NC}) \right]^2. \tag{30}
\]

Due to the effect that the magnons in the left FI is not condensed \( \langle a_L \rangle = 0 \), the magnon current arises from the \( O(J_{ex}) \)-term and it becomes essentially the dc magnon current. These are in sharp contrast to the C-P and C-C junctions.

Tuning

\[
\hbar \Omega = g \mu_B B_L, \tag{31}
\]

the amount \( \langle I \rangle_{NC-P} \) becomes maximally.

B. Indirect FMR

Eq. (31) indicates that tuning \( \hbar \Omega = g \mu_B B_L \), an indirect FMR does occur in the left FI. Any microwaves are not directly applied to the left FI (Fig. 5). Nevertheless, a FMR does occur in the left FI since the applied microwave to the right FI can still affect the spins of the left FI via the exchange interaction \( H_{ex} \) [Eq. (3)]. The applied microwave forces the spins of the right FI to precess coherently with the frequency \( \Omega \) and excite the zero-mode of magnons [Eqs. (4) and (5)] in Sec. II B. Those pumped magnons propagate and interact with the (boundary) spins in the left FI via \( H_{ex} \), and produce the zero-mode of magnons with the frequency \( \Omega \), which have the same frequency with the microwave directly applied to the right FI. Thus, the applied microwave to the right FI can indirectly affect the left FI via the pumped magnons and generate the indirect FMR.

C. Distinctions from C-C and C-P junctions

Focusing on the distinction from the C-P and C-C junctions, we summarize the features of magnon currents in the NC-P junction (Fig. 5).

The main point is that in the NC-P junction, the magnon currents arise as \( \langle I \rangle_{NC-P} = O(J_{ex}^2) \) [Eq. (30)]. This is in sharp contrast to the C-C and C-P junctions. Therefore even when we apply an electric field to the interface, the resulting A-C phase cannot play any roles on magnon transport in any significant manners. This is in sharp contrast to the C-C and C-P junctions, where the A-C phase can play the key role on the ac/dc conversion of the magnon currents \( O(J_{ex}) \).

Another distinction is that the magnon current of the NC-P junction becomes essentially the ac one [Eq. (30)]. The noncondensed magnons generate the dc magnon current from the applied ac magnetic field. Even when a static [i.e., time-independent \( dB_{L(R)}/dt = 0 \)] magnetic field gradient is produced, \( B_L - B_R \neq 0 \), the resulting magnon current becomes the dc one. This is in sharp contrast to the C-C and C-P junctions, where the magnon current can become the ac one due to the reason addressed in Sec. II B. As stressed, the conversion of the ac and dc magnon currents in the C-P junction is characterized not by the magnetic fields, but by the relation between \( g \mu_B B_L / \hbar \) and \( \Omega \). Therefore, if \( g \mu_B B_L / \hbar \neq \Omega \), the magnon current becomes an ac one even in that case.

Finally, comparing the maximum magnon current densities available in each hybrid junction, we clarify the quantitative effect of microwave pumping on the generation of magnon currents; \( \langle I \rangle_{NC-P}, \langle I \rangle_{C-P} \), and the one of the C-C junction \( \langle I \rangle_{C-C} \). Assuming \( J_{ex} = 0.1 \mu eV, \alpha = 1 \AA, S = 15, g = 2, \tau_{p(NC)} = 100 \text{ns}, \) the magnon-BEC density [Eq. (23)] \( n_L \sim 10^{19} \text{cm}^{-3} \), and \( \Gamma_0 = 0.5 \mu T \), each ratio on the direct and the resulting indi-
The amount becomes maximally on FMR $B_L = B_R = h\Omega/(g\mu_B)$ becomes

$$
|\langle I\rangle_{\text{NC-P}} / |\langle I\rangle_{\text{C-P}} | \simeq 1.1 \times 10^5, \quad (32a)
$$

$$
|\langle I\rangle_{\text{NC-P}} / |\langle I\rangle_{\text{C-P}} | \simeq 3.6 \times 10^6. \quad (32b)
$$

These give

$$
|\langle I\rangle_{\text{C-P}} | \ll |\langle I\rangle_{\text{NC-P}} | . \quad (33)
$$

This shows that the magnon injection through microwave pumping and the resulting FMRs drastically enhances the magnon current. In addition to the direct FMR, due to the indirect FMR in the adjacent left FI (Sec. III B), the magnon current of the NC-P junction (Fig. 5) can become much larger than that of the C-P junction.

### IV. MAGNON CURRENT THROUGH AHARONOV-CASHER PHASE

Lastly, using microwave pumping, we discuss the possibility that a magnon current through the A-C phase flows persistently$^4,26,27$ even at finite (room) temperature. In Ref. $^3$, using magnon-BEC$^6,5$, we have found that the A-C phase$^{22,27}$ generates a persistent magnon-BEC current at zero-temperature. Since both magnon condensate and pumped magnons correspond to the macroscopic coherent precession$^2$, in terms of spin variables, it is expected that a similar magnon current arises from microwave pumping. Therefore, based on the microscopic description of microwave pumping in Sec. III B, we consider finite temperatures and evaluate the magnon current driven by an A-C phase.

To this end, we revisit the discussion of Ref. $^2$, and expand it by taking the effect of microwave pumping into account. We consider a single FI described by the Hamiltonian $\mathcal{H}_{\text{FI}}$ [Eq. (11)] and apply now an electric field $E$ along the $y$-axis $\mathbf{E}(r) = E_y \mathbf{e}_y$ as well as a homogeneous magnetic field $B$ along the $z$-axis. A magnetic dipole $g\mu_B \mathbf{e}_z$ (i.e., magnon) moving along a path $\nu$ in an electric field $\mathbf{E}(r)$ acquires a Berry phase$^{33,35}$, called the A-C phase$^{25}$,

$$
\theta_{\text{A-C}} = \frac{g\mu_B}{\hbar c^2} \int_{\nu} d\mathbf{l} \cdot [\mathbf{E}(r) \times \mathbf{e}_z]. \quad (34)
$$

Since $\mathbf{E}(r) = E \mathbf{e}_y$, it becomes $\mathbf{E}(r) \times \mathbf{e}_z = E \mathbf{e}_x$. Therefore we focus on magnon transport along the $x$-axis, which is essentially described$^{26,27}$ by the Hamiltonian

$$
\mathcal{H}^{\text{A-C}}_{\text{FI}} = -JS \sum_j (a_j a_j^\dagger e^{-i\theta_{\text{A-C}}} + \text{H.c.}) + g\mu_B B \sum_j a_j a_j^\dagger.
$$

The summation is over all spins along the $x$-axis. The A-C phase reads $\theta_{\text{A-C}} = (g\mu_B/(\hbar c^2)) E \alpha$.

We then continue to apply microwave $\Omega$ [Sec. III B] and generate a macroscopic coherent precession described by Eq. (11). Consequently, the A-C phase induces a magnon current analogous to the magnon-BEC current$^6$. The amount becomes maximally on FMR $h\Omega = g\mu_B B$ (Fig. 3). The resulting magnon current density induced by the A-C phase reads

$$
\langle I \rangle = \frac{2JS}{\hbar} (n)_P \sin\theta_{\text{A-C}}, \quad (35)
$$

where $\langle n\rangle_P = \frac{8\hbar}{(\tau g\mu_B \Gamma_0)} \frac{\gamma_0^3}{\hbar^2} (\gamma_0^3 \hbar T)^2 \propto T^2$ [Eqs. (10) and (18)].

Using the above single FI and microwave pumping, we form a ring consisting of a cylindrical wire analogous to the magnon-BEC ring. Then, it is expected that the magnon current flows like the persistent$^2$ magnon-BEC current (we refer for further details of the magnon-BEC ring where the current is quantized to Ref. $^7$). We point out the possibility that due to microwave pumping, the magnon current might flow even at finite temperatures. Dissipation$^{4,5,41,42}$ would arise at finite temperature due to the coupling with thermal bath e.g. due to lattice vibrations (i.e., phonons), but such detrimental effects can be compensated by magnon injection$^{26,27}$ through microwave pumping where the pumping rate [Eqs. (7) and (13)] is larger than the dissipative decay rate.

Assuming$^3,33,34$ $\alpha = 1$ Å, $S = 16$, $g = 2$, $\tau_p = 100$ ns, $\Gamma_0 = 0.5\mu T$, $\gamma_0^3 \simeq 5 \times 10^{-4}$ ev$^{-1}$ (Sec. III B 2), $T = 300$ K, and $J_{m-m} = 30$ μev, they amount to $\langle n\rangle_P \simeq 1.28 \times 10^{22}$ cm$^{-3}$ and $\langle n\rangle^{P-m}_P \simeq 3 \times 10^{21}$ cm$^{-3}$. The magnon current [Eq. (35)] becomes much larger, about $10^3$ times, than the magnon-BEC current$^7$. Using the same setup (i.e., cylindrical wire) with Ref. $^7$, the electric field$^{6,40}$ of the order of $nV/m$ is induced (see Sec. III C) and consequently, the voltage drop amounts to the order of $\mu V$, which is actually much larger than the one arising from the magnon-BEC current ($\sim nV$). Thus, we expect the direct measurement of such magnon currents to be experimentally more realizable.

### V. SUMMARY

We have constructed a microscopic theory on magnon transport through microwave pumping in FIs. Due to the magnon-magnon interaction, the non-zero mode of magnons are excited and the number density of such microwave pumped magnons (P) increases when temperature rises. Dissipations$^{4,5,41,42}$ would arise at finite temperature due to the coupling with thermal bath e.g. due to lattice vibrations (i.e., phonons), but such detrimental effects can be compensated by magnon injection$^{26,27}$ through microwave pumping where the pumping rate [Eqs. (7) and (13)] is larger than the dissipative decay rate.
indirect FMRs, the NC-P junction becomes the best one (among the C-C, C-P, and NC-P junctions) to generate the largest magnon current. In a single FI, microwave pumping can produce a magnon current through a Berry phase (i.e., the Aharonov-Casher phase) even at finite temperature in the presence of magnon-magnon interactions. The amount of such magnon currents increases when temperature rises, since the number density of pumped magnons increases. Due to FMR, the amount becomes much larger, about $10^3$ times, than the magnon-BEC current.

46 This proves that low temperatures are not required, which may be of crucial importance in view of applications.

47 Regarding the theoretical aspects of their quasi-equilibrium magnon-BECs, see Refs. [17–19,44,45] and also references therein.

48 Since we apply a weak microwave $| \Gamma_0/B_{L(0)} | \sim 10^{-5}$, the Holstein-Primakoff transformation is applicable.

49 We assume that the dipole-dipole interaction is negligible compared to the magnon-magnon interaction.

50 Since Serga *et al.* have reported that the decay time of quasi-equilibrium magnon condensate is much longer than that of pumped magnons, we here assume that the life-time of quasi-equilibrium magnon condensate is infinite.

51 Regarding the detail, see Ref. [7].
