X-ray and optical observations of three clusters of galaxies: Abell 901, Abell 1437, and Abell 3570

Sabine Schindler

Abstract. We analyse three clusters of galaxies, Abell 901 (z=0.17), Abell 1437 (z=0.13) and Abell 3570 (z=0.037). They have low to intermediate X-ray fluxes and an irregular morphology in the ROSAT All-Sky Survey (RASS). These clusters are chosen to test the abilities and limitations of the RASS in terms of cluster fluxes and cluster morphologies. Therefore some “worst” cases are used here. X-ray observations with the ROSAT/HRI and optical spectroscopic observations are carried out. The ROSAT/HRI observations, which have a much better spatial resolution than the RASS, reveal in two of the three cases a significantly different morphology than seen in the RASS. The reasons are point sources which could not be resolved in the RASS and were therefore confused with the cluster emission. For A3570 we could confirm the relaxed state of the cluster by the optical determination of a small velocity dispersion. In the cluster with the lowest flux (Abell 901) the countrate measurement is strongly affected by point sources, in the two other cases the countrate measurements of the RASS are reliable, i.e. they are reproduced by the ROSAT/HRI measurement. We conclude that for clusters with a flux of a few times $10^{-12}$ erg/cm$^2$/s or smaller, which show at the same time a non-relaxed morphology, the flux measurement of the RASS can be seriously affected by fore- or background sources. We point out that an all-sky survey of a second ABRIXAS mission would provide a much clearer source distinction for low-flux clusters and thus a much improved countrate determination.

1. Introduction

Clusters of galaxies are excellent probes for cosmological theories. Different cosmological models predict vastly different properties for the clusters as a function of redshift. Therefore relations of cluster properties, their distributions and evolution can be used to constrain cosmological parameters. Selection according to X-ray luminosity is a good way to find the highest mass concentrations because of a relatively well defined correlation between the X-ray luminosity and the total cluster mass (Reiprich & Böhringer 1999; Schindler 1999). A second advantage of high luminosity clusters is, of course, that they require shorter exposure times than their fainter counterparts to get the same numbers of photons. Therefore many X-ray studies have concentrated so far on luminous clusters.

But also low-luminosity clusters are interesting for different reasons. For example, low-luminosity clusters are the links between massive clusters and groups of galaxies. Groups differ in various properties from clusters. Their $L_X - T$ relation is steeper than the one for clusters (compare Ponman et al. 1996 with Arnaud & Evrard 1999), their gas mass fraction is smaller (compare Pildis et al. 1995 and Ettori & Fabian 1999 or Mohr et al. 1999) and their silicon abundance is lower (Fukazawa et al. 1998). To investigate the physics causing these differences it is important to understand how these properties change with mass or X-ray luminosity.

Low-luminosity clusters are also needed to determine the slope of various relations well. With a long leverage the slope of a relation can be determined more accurately, therefore the luminosities should preferably span several orders of magnitude. For other studies, e.g. the determination of the correlation function or distribution of properties, large samples of clusters are desirable to get the most accurate results. Therefore, when large numbers are required also faint clusters must be taken into account.

Nearby low-luminosity clusters sometimes provide problems. Not only is the countrate determination more sensitive to the background subtraction, but also contamination by other fore- and background sources can become critical, in particular when the cluster shows asymmetries and substructure. The degree of source confusion affecting morphological studies and countrate determinations depends on the sensitivity and the resolution of the detector. Already the factor of 5 between the point spread function (PSF) of the ROSAT/PSPC and the ROSAT/HRI can
make a big difference, in particular for low-flux clusters (compare the ROSAT/PSPC observation of Cl0939+4713 (Schindler & Wambsganss 1996) and the corresponding ROSAT/HRI observation (Schindler et al. 1998)). In the RASS (Voges et al. 1996) the spatial resolution is even more critical because the source is not always in the centre of the field-of-view, where the detector has the best spatial resolution, like in most pointed observations. But the source is observed at different off-axis angles as the detector scans the sky. The radius including 50% of the photons increases by about a factor of 13 when moving from the centre to the border of the ROSAT/PSPC. As the final image of a source is composed of many PSFs the final 50% radius in the RASS is about 80″, i.e. about six times larger than the on-axis PSPC resolution (depending also on the energy).

Clusters which have low fluxes because they are far away, are also very interesting, in particular for cosmological applications. But their extent in the sky is much smaller than for nearby clusters and thus they are less affected by source confusion. Therefore, we concentrate this investigation on nearby clusters with low to intermediate luminosity.

Three clusters – A901, A1437 and A3570 – were selected for a detailed look with the high resolution of the ROSAT/HRI and for optical observations. Each of the clusters shows irregular structure in the RASS. This investigation does of course not show representative RASS clusters, but it is a “worst-case” study. For RASS clusters with high flux and/or regular shape countrate determinations are straightforward and reliable.

The paper is organised as follows. After a description of the observations (Sect. 2) we present the analysis of the optical data in Sect. 3 and the analysis of the X-ray data in Sect. 4. Finally, Sect. 5 gives our summary and conclusions. Throughout this paper we use $H_0 = 50$ km/s/Mpc and $q_0 = 0.5$.

For two of the clusters – A901 and A3570 – optical spectra could be taken. In A901 redshifts of three galaxies could be well determined. These three galaxies are at similar redshifts (see Table 2). We derive a cluster redshift of $z_{A901}=0.17$. Unfortunately, the number of galaxies is not sufficient to estimate the velocity distribution.

In A3570 we found 17 cluster member galaxies (see Table 3) in addition to the three galaxies known previously (Postman & Lauer 1995). From these 20 galaxies we derive a cluster redshift $z_{A3570}=0.0375$ (very similar to the redshift 0.0372 by Abell et al. 1989). The velocity distribution is shown in Fig 1. The velocity dispersion based on these 20 galaxies $\sigma = 460$km/s is relatively small. Such a small velocity dispersion is a first hint for a virialised state of the cluster. If merging of subclusters would take place and not all of the mergers would happen perpendicular to the line-of-sight a broad velocity distribution would be expected. Assuming virial equilibrium we estimate the cluster mass from the velocity dispersion and the estimate of the virial radius by Girardi et al. (1998) to $M_{\text{vir}}(A3570) = 2.7 \times 10^{14} M_\odot$.

### 3. Optical analysis

#### 3.1. Abell 901

A ROSAT/HRI image of a 21′ region around A901 shows several sources (Fig. 1). A901 turns out to have a very compact structure contrary to the previous conclusion from the RASS. Ebeling et al. (1996) list A901 as a double cluster. Their so-called “brighter subcluster” turns out to be a number of point-like sources, while the true cluster emission is what they call the “fainter subcluster”. In Fig. 2a six X-ray point sources with a signal-to-noise ratio of at least 3 are indicated. For three of them optical counterparts can be found on ROE/NRL COSMOS finding charts (see Fig. 2b and Table 4). Unfortunately, for none of these counterparts optical spectra could be taken.

### 4. X-ray analysis

#### 4.1. Abell 901

A ROSAT/HRI image of a 21′ region around A901 shows several sources (Fig. 1). A901 turns out to have a very compact structure contrary to the previous conclusion from the RASS. Ebeling et al. (1996) list A901 as a double cluster. Their so-called “brighter subcluster” turns out to be a number of point-like sources, while the true cluster emission is what they call the “fainter subcluster”. In Fig. 2a six X-ray point sources with a signal-to-noise ratio of at least 3 are indicated. For three of them optical counterparts can be found on ROE/NRL COSMOS finding charts (see Fig. 2b and Table 4). Unfortunately, for none of these counterparts optical spectra could be taken.
Table 2. Redshifts and positions of galaxies in the clusters A901 and A3570.

| cluster | α(J2000) | δ(J2000) | redshift |
|---------|----------|----------|----------|
| A901    | 09 54 57.5 | -10 11 50 | 0.171    |

Fig. 1. Velocity distribution of 20 galaxies in A3570

because the optical observations were carried out before the X-ray observations. At the position of A902 (2′ West of F) no X-ray emission can be detected.

The optical centre of A901 determined by Abell et al. (1989) is located between the X-ray position of A901 and source A. To test the extent of the X-ray emission of A we derive an X-ray profile (see Fig. 4a). The profile is compared with the on-axis PSF of the ROSAT/HRI. The profile of A is only slightly more extended than the on-axis PSF, which is expected for a point source 6′ away from the pointing position. Therefore, we conclude that most likely the X-ray emission from A is point-like and therefore not (sub-)cluster emission, but probably emission from an active nucleus in the centre of a galaxy. The most likely candidate for this AGN is a galaxy of 16.6′′ in B (see Table 4). This galaxy is located at a distance of 5′′ from the cluster emission – a distance smaller than the pointing accuracy of ROSAT.

The only cluster emission is coming from the region indicated by “A901” in Fig. 2b (α2000 = 09h 55m 57.0s, δ2000 = −09° 58′ 59″). This emission is shown magnified in Fig. 3 on a scale of 1.4′. The emission is very compact, but not point-like, as can be clearly seen from the comparison of the cluster profile and PSF (see Fig. 3a). A β-model fit to the cluster profile (Cavaliere & Fusco-Femiano 1976; Jones & Forman 1984) reveals an extremely small core radius of 0.10 ± 0.03′ or 22 ± 5kpc (see also Table 4) reflecting the compactness of the emission.

The X-ray emission of A901 can be traced out to a radius of almost 2′, corresponding to 430 kpc. Within this radius a countrate of 0.059 ± 0.002 cts/s is found. If the emission of A901 and the 6 point sources is summed up, the total countrate is at least a factor 1.8 larger than the cluster countrate, i.e. the cluster countrate would be largely overestimated if the point sources were not resolved. For the flux and luminosity shown in Table 4 only the cluster emission of A901 was used.

Estimating a temperature of 4 keV from $L_X - T$ relations (Allen & Fabian 1998; Markevitch 1998; Arnaud & Evrard 1999) and assuming hydrostatic equilibrium we estimate the total mass at the outer radius $M_{gal}(r < 430 kpc) \approx 9 \times 10^{13} \text{M}_\odot$. The gas mass is $M_{gas}(r < 430 kpc) = 1.2 \times 10^{13} \text{M}_\odot$, i.e. the gas mass fraction is about 13%.

Obviously, A901 with a flux of $f_X(0.1-2.4 \text{keV}) = 3.0 \times 10^{-12} \text{erg/s/cm}^2$ is falsely in the RASS X-ray brightest Abell cluster sample of Ebeling et al. (1996) as this sample has a flux limit of $5 \times 10^{-12} \text{erg/s/cm}^2$. Ebeling et al. list a flux of $5.2 \times 10^{-12} \text{erg/s/cm}^2$ for the “brighter subcluster”, which is in reality not cluster emission. For the “fainter subcluster”, which is the true A901 emission, they list correctly $3.0 \times 10^{-12} \text{erg/s/cm}^2$, but this value is far below their flux limit.

The compact (but not point-like) nature of the X-ray emission of A901 was used.

The compact (but not point-like) nature of the X-ray emission of A901 was used.
Fig. 2. Region around A901. a) X-ray image taken with the ROSAT/HRI. Apart from the extended emission of A901 six point-like sources (A–F) are visible (see also Table III). b) Optical image from the Digitized Sky Survey of the same size as a). The X-ray sources A, C and F could be identified with optical counterparts (see Table III).

Fig. 4. Radial profiles of two clusters. Left: A901. The filled circles show the cluster profile with the corresponding fit (full line). The crosses show the profile of the source A. For comparison the on-axis PSF of the ROSAT/HRI normalised to the central bin is shown (dashed line). As the source A is not exactly in the centre of the pointing but 6′ away, the profile is expected to be slightly more extended than the dashed line as seen here. Therefore A is probably a point source. Right: A1437. Due to the asymmetry of the cluster, fit curves for different 90° sectors are derived, sector 10°–100° (dash-dotted line) (N over E), sector 100°–190° (dotted line), sector 190°–280° (long-dashed line), sector 280°–370° (long dash-dotted line). For clarity only the data points of the profile averaged over all sectors are shown. The corresponding fit curves are the full line for a fit of all data points and the short-dashed line for a fit excluding the two innermost data points. To make these different inner radii visible in the figure, the curves start at the radius that was used as the inner radius for the fit.
about $t_{\text{cool}} \approx 10^9$ years. Therefore it is possible, that the compact X-ray emission is caused by a cooling flow.

4.2. Abell 1437

The cluster A1437 at a redshift $z=0.1339$ (Struble & Rood 1987) is the most X-ray luminous cluster of this sample. The cluster centre in X-rays (see Table 3) does not coincide with the optical position: Abell et al. (1989) determined a position 45$'$ in the SE of the X-ray maximum. The emission of the cluster is strongly elongated in SW-NE direction (see Fig. 3). This elongation can be seen as well in the RASS. The RASS distinguishes also easily the point source in the NE, for which an optical counterpart can be found on APM finding charts (see Table 3). Although the cluster shape is not exactly elliptical, we fit ellipses to the isophotes (Bender & Moellenhof 1987) to estimate the elongation. The position angle varies around 55$^\circ$ (N over E). The minimum axis ratio of 0.38 is reached at 0.01 cts/s/arcmin$^2$. At this level the centre of the ellipse is shifted 35$''$ to the west and 36$''$ to the south with respect to the position of the X-ray maximum.

The fit parameters of the surface brightness profile are not well constrained (see Table 3) because of the non-spherical morphology of the cluster. Therefore, radial profiles of the cluster emission are determined in four different sectors using as centre the X-ray maximum listed in Table 3 and subsequently fitted with $\beta$ models (see Fig. 4b). The two central bins show some excess emission. This excess cannot come from a cooling flow because the central cooling time is about $2 \times 10^{10}$ years. It is probably a small contamination by an AGN. Because of this excess we try to fit the overall profile with and without these two bins. The results are listed in Table 3. In both – the fit parameters and the fit curves – it is obvious, that the cluster is very asymmetric.

Such asymmetries can arise during a merger of subclusters. From combined N-body and hydrodynamic simulations it is known that such elongated morphologies are common shortly after the collision of two subclusters, when the intra-cluster gas is squeezed out perpendicular to the collision axis (Schindler & Müller 1993).

The X-ray emission can be traced out to about 9$'$. After excluding the point source in the NE a countrate of 0.25 $\pm$ 0.01 cts/s is found. This corresponds to a flux of $f_X(0.1-2.4\text{keV}) = (1.04 \pm 0.03) \times 10^{-11}\text{erg/s/cm}^2$. For A1437, which is the most luminous cluster of this sample, the flux determination from the RASS ($f_X(0.1-2.4\text{keV}) = 1.02 \times 10^{-11}\text{erg/s/cm}^2$ (Ebeling et al. 1996) and $f_X(0.1-2.4\text{keV}) = 1.00 \times 10^{-11}\text{erg/s/cm}^2$ (Ebeling et al. 1998), respectively) is reliable. Also the morphological determination from the RASS is good: the point source in the NE can be distinguished easily and the elongated shape of the cluster is visible in the RASS as well.

4.3. Abell 3570

The cluster A3570 is the nearest cluster of this sample ($z = 0.037$). The X-ray emission is faint and the extent is of the same order as the field-of-view of the ROSAT/HRI. With small smoothing the cluster X-ray emission is hardly visible, because the region is dominated by discrete sources (see Fig. 3a and Table 3). One of the
We analysed three clusters of galaxies with low to intermediate X-ray luminosities which show an irregular appearance in the ROSAT All-Sky Survey. As the confusion with foreground and background sources is increasingly critical with decreasing flux and increasing substructure of the cluster, we test the limitations of the RASS. With only three clusters, of course, this cannot be a statistical study, but it is meant to be a “worst-case” study. We would like to stress that for higher flux values source confusion is less important and that for clusters with these fluxes the RASS results are very reliable.

The results of the follow-up observations – X-ray observations with the ROSAT/HRI and optical spectroscopic observations – are summarized in Table 3. The ROSAT/HRI observations, which have a much better spatial resolution than the RASS, revealed in two of the three cases a different morphology than seen in the RASS. The reasons are point sources which could not be resolved in the RASS and were therefore confused with the cluster emission. In one of the three clusters the countrate measurement is affected by the point sources, in the two other cases the countrate measurements of the RASS are reliable. The results for the three clusters are the following:

- Abell 901: With a flux of $f_X(0.1-2.4\text{keV}) = 3.0 \pm 0.1 \times 10^{-12}\text{erg/cm}^2/\text{s}$ this cluster is the faintest one in the sample. Both the measurement of the countrate and the determination of the morphology provide difficul-

Table 4. Positions and identification of non-cluster X-ray sources in the pointings

ties in the RASS. Several discrete sources cannot be distinguished from the cluster emission in the RASS. With the RASS information only it was concluded that this cluster consists of two subclumps (Ebeling et al. 1996), while the true cluster X-ray emission is very compact (\( r_c = 22 \)kpc). The countrate would be over-estimated by at least 80% if the discrete sources cannot be separated from the cluster.

- Abell 1437: This cluster has the highest flux of all the clusters in the sample \( f_X(0.1-2.4\text{keV}) = 1.04 \pm 0.03 \times 10^{-11} \text{erg/cm}^2/\text{s} \). With such a high flux the RASS results are very reliable. There is no problem with the countrate or morphology determination. The point source in the NE of the cluster can easily be distinguished in the RASS.

- Abell 3570: This cluster has several point sources superposed on the cluster emission. Although the countrate determination is not affected by these sources (their countrate is only 1% of the cluster countrate) the true morphology is very regular in contrast to the impression from the RASS. Optical measurements of the cluster galaxies give a very small velocity dispersion confirming the picture of a relaxed cluster.

We conclude that for clusters with fluxes less than a few times \( 10^{-12} \text{erg/cm}^2/\text{s} \), which have at the same time an irregular morphology, the confusion with fore- and background sources can be a problem in the RASS. So mor-
Table 5. Summary of the properties of the three clusters. For the flux and luminosity calculation hydrogen column densities from Dickey & Lockman (1990, see last line) were used and temperatures were estimated from $L_X - T$ relations (Allen & Fabian 1998; Markevitch 1998; Arnaud & Evrard 1999): $T = 4.2^{+0.5}_{-0.7}$ keV for A901 and A3570, $T = 6^{+3.2}_{-0.8}$ keV for A1437.
