Single Mott Transition in Multi-Orbital Hubbard Model

A. Liebsch
Institut für Festkörperforschung, Forschungszentrum Jülich, 52425 Jülich, Germany

The Mott transition in a multi-orbital Hubbard model involving subbands of different widths is studied within the dynamical mean field theory. Using the iterated perturbation theory for the quantum impurity problem it is shown that at low temperatures inter-orbital Coulomb interactions give rise to a single first-order transition rather than a sequence of orbital selective transitions. Impurity calculations based on the Quantum Monte Carlo method confirm this qualitative behavior. Nevertheless, at finite temperatures, the degree of metallic or insulating behavior of the subbands differs greatly. Thus, on the metallic side of the transition, the narrow band can exhibit quasi-insulating features, whereas on the insulating side the wide band exhibits pronounced bad-metal behavior. This complexity might partly explain contradictory results between several previous works.

I. INTRODUCTION

The nature of the metal insulator transition in multiband materials involving subbands of different widths is not yet fully understood. As a result of the geometric complexity of many transition metal oxides, the degeneracy of valence bands is frequently lifted, giving rise to coexisting narrow and wide partially filled bands. A key issue in these materials is therefore whether these subbands exhibit separate Mott transitions or whether single-particle hybridization among subbands and inter-orbital Coulomb interactions ensure the occurrence of a common transition involving all subbands simultaneously. An example is the layer perovskite Sr$_2$RuO$_4$ which consists of a wide, two-dimensional $d_{xy}$ band and narrow, nearly one-dimensional $d_{xz,yz}$ bands. This system is believed to exhibit unconventional p-wave superconductivity. Isotopic replacement of Sr by Ca leads to a distortion of oxygen octahedra and an effective narrowing of the Ru-derived $t_{2g}$ bands, causing a metal insulator transition.

Another case is the layer compound Na$_x$CoO$_2$ which as a function of doping concentration exhibits a wide range of properties, including superconductivity (when hydrated), while the parent material CoO$_2$ is an insulator.

In previous work we investigated the Mott transition in Ca$_{2-x}$Sr$_x$RuO$_4$ by considering a 3-band model appropriate for Sr$_2$RuO$_4$ and varying the on-site Coulomb interaction rather than modifying the band width. Extending earlier quasi-particle calculations for this system within the dynamical mean field theory (DMFT) we found that inter-orbital Coulomb interactions lead to a significant redistribution of spectral weight between $t_{2g}$ orbitals. As a result, despite the completely different shapes and widths of the single-particle densities of states, for increasing $U$ the $d_{xy}$ and $d_{xz,yz}$ subbands exhibit similar correlation features, suggesting the existence of a single Mott transition. Additional single-particle coupling between $t_{2g}$ states caused by octahedral distortions undoubtedly will enhance the trend towards a single transition. This result was in conflict with DMFT calculations by Anisimov et al. who obtained a sequence of Mott transitions as the on-site Coulomb interaction was increased beyond the single-particle widths of the narrow and wide $t_{2g}$ subbands of Sr$_2$RuO$_4$, respectively.

To avoid the uncertainties stemming from the maximum entropy reconstruction of real-frequency spectra we recently considered a simple two-band model and focused on quantities directly available from the Quantum Monte Carlo (QMC) calculations carried out at imaginary times and frequencies. The subbands were assumed to have semi-circular density of states of widths $W_1 = 2$ eV, $W_2 = 4$ eV, to be each half-filled, and to interact only via local intra- and inter-orbital Coulomb energies $U$ and $U' = U - 2J$, where $J$ is the Hund’s rule exchange integral. The quantum impurity calculations were performed within the DMFT and multi-orbital QMC method for $T = 125$ meV. For increasing $U$ and $U'$ (with fixed $J = 0.2$ eV) the subband quasi-particle weights $Z_i$ were found to vanish at about the same critical $U_c$, within a characteristic uncertainty caused by critical slowing down. The same behavior was found for the quantities $G_i(\beta/2) (\beta = 1/k_BT)$ which define the spectral weight of the coherent subband peaks within a few $k_BT$ of $E_F$. Also, two-band calculations at $T = 0$ within the iterated perturbation theory (IPT) supported the existence of a common transition. These results confirmed our previous finding, namely, that inter-subband coupling due to local Coulomb interactions gives rise to a single Mott transition rather than a sequence of orbital-selective transitions.

Recently Koga et al. considered the same two-band Hubbard model involving semi-circular densities of states with $W_1 = 2$ eV, $W_2 = 4$ eV and on-site Coulomb interactions specified by $U = U' = 2J$. Also assuming both subbands to be half-filled, they studied the effect due to larger Hund’s rule coupling by choosing $J = U/4$ and $U' = U/2$. To be able to reach lower temperatures, the DMFT calculations were performed within the exact diagonalization (ED) method and a linearized two-site version of the DMFT. Surprisingly, both impu-
metal insulator transitions, i.e., the narrow subband exhibits a smaller critical $U_c$ than the wide subband, implying a region of coexisting metallic and insulating sub-bands in spite of the inter-orbital Coulomb interactions defined by $U'$ and $J$.

The conflicting results obtained within these various approaches underline the subtle and complex nature of the Mott transition in multi-orbital systems. Since the non-isotropic multi-band character among transition metal oxide materials is the rule rather than an exception there is evidently a need to clarify this fundamental issue. Further theoretical studies are required to test the reliability of the DMFT method and various quantum impurity treatments. Contradictory results for a rather simple model which nevertheless captures a key feature present in many real systems obviously shed doubts on predictions obtained for more complex materials.

In the present work we reconsider the same two-band Hubbard model as in Refs. 11 and 13. Since the QMC calculations are difficult to perform at low temperatures, we consider first the simpler iterated perturbation theory at finite $T$. Although this scheme is not reliable on a quantitative level, it can serve as a useful guide for qualitative purposes. At sufficiently low temperatures, the IPT reveals a single first-order transition for both subbands, confirming our previous results. Because of the numerical simplicity of this model we are able to obtain the entire $T - U$ phase diagram. We then study the same model within the two-band QMC method. Although convergence is considerably more difficult at low temperatures, these results also suggest a common Mott transition. On the other hand, the interpretation of this multi-band phase transition is complicated since in both phases the subbands exhibit quite different correlation features due to their different single-particle properties. Thus, in the metallic phase, the narrow band is much more correlated than the wide band and shows a mixture of both metallic and insulating features. Similarly, in the insulating phase the narrow band exhibits a gap while the wide band reveals pronounced bad-metal behavior. Thus, the transition is partially incomplete for individual subbands. This complexity of the quasi-particle spectra, and the difficulty of clearly identifying metallic and insulating properties at finite temperatures, presumably is the origin of some of the contradictions between the previous works.

The outline of this paper is as follows. In the next section we discuss the DMFT results derived within the IPT as a function of temperature. Section III contains the results obtained for the QMC method. Section IV provides a summary.

II. IPT – DMFT

Let us consider the paramagnetic metal insulator transition in a two-band Hubbard model consisting of sub-bands of width $W_1 = 2$ eV and $W_2 = 4$ eV. The densities of states are assumed to be semi-circular: $\rho_\uparrow(\omega) = 4/(\pi W_1^2)\left(1 - 4\omega^2/W_1^2\right)^{1/2}$, corresponding to non-hybridizing Bethe lattices. Both bands are taken to be half-filled. The interacting Green’s functions at imaginary frequencies are defined as

$$G_i(i\omega_n) = \int d\omega \frac{\rho_i(\omega)}{i\omega_n + \mu - \omega - \Sigma_i(i\omega_n)}, \quad (1)$$

where $\omega_n \geq 0 = (2n+1)\pi k_B T$ are Matsubara frequencies and $\mu$ is the chemical potential. $\Sigma_i(i\omega_n)$ are the subband self-energies which must be determined self-consistently. Removal of the self-energy from the central site yields the impurity Green’s functions

$$g_i(i\omega_n) = \left[G_i^{-1}(i\omega_n) + \Sigma_i(i\omega_n)\right]^{-1}. \quad (2)$$

The corresponding Fourier transforms at imaginary times are denoted as $g_i(\tau)$. Since both bands are assumed to be symmetric and half-filled, these functions satisfy the conditions $g_i(0) = g_i(\beta) = -0.5$ and $g_i(\tau) = g_i(\beta - \tau)$. For purely on-site Coulomb interactions specified by intra- and inter-orbital matrix elements, the self-energy components in second-order perturbation theory are

$$\Sigma_i(i\omega_n) = \int_0^\beta d\tau e^{i\omega_n \tau} \left[\sigma_1 g_i^1(\tau) + \sigma_2 g_i^2(\tau)\right], \quad (3)$$

where $j = 1(2)$ for $i = 2(1)$ and the coefficients $\sigma_i$ are defined as $\sigma_1 = U^2$ and $\sigma_2 = J^2 + 2(U'^2 + J^2 - U' \cdot J)$. Since we take both subbands to be half-filled we do not consider here corrections to the bare second-order self-energy which should be introduced in the absence of particle-hole symmetry. At half-filling, the first-order Hartree-Fock terms are identical for both bands, $\Sigma_i^{\text{HF}} = 1.5U - 2.5J$, and can be absorbed by the chemical potential. Throughout this paper we assume $J = U/4$ and $U' = U/2$, unless noted otherwise.

The self-energies $\Sigma_i(i\omega_n)$ are now inserted in Eq. (1) and the procedure is iterated until self-consistency is achieved. The starting self-energy is taken to be zero. In particular at low temperatures, the direct and inverse Fourier transforms must be done with sufficient accuracy. Also, at each iteration the symmetry condition $g_i(\tau) = g_i(\beta - \tau)$ is enforced to remove spurious effects due to numerical inaccuracies. This ensures that the $\Sigma_i(i\omega_n)$ remain purely imaginary as they should be for symmetric half-filled bands. Typically $L = 256$ time slices and $2^{12}$ Matsubara frequencies were used. Also, the real-$\omega$ integration in Eq. (1) must be performed on a rather fine mesh in order to capture the narrow coherent peak close to the metal insulator transition. This can be achieved by linearly interpolating $\rho_i(\omega)$ and performing the $\omega$ integral analytically between mesh points. Once a converged solution is found, the Green’s functions $G_i(i\omega_n)$ are used to generate the Fourier transforms $G_i(\tau)$ from which the quasi-particle spectra at real frequencies are derived via the maximum entropy method.
FIG. 1: Quasi-particle weights $Z_i$ of two-band Hubbard model as a function of on-site Coulomb energy $U$ for $T = 0.01$ eV, calculated within IPT-DMFT. Solid (open) dots: $Z_1 (Z_2)$. (a) increasing $U$, (b) decreasing $U$.

FIG. 2: Same as Fig. 1 except for $T = 0.02$ eV.

FIG. 3: Same as Fig. 1 except for (a) $T = 0.03$ eV and (b) $T = 0.04$ eV. Each Figure shows the hysteresis obtained for increasing $U$ (upper points) and decreasing $U$ (lower points).

Figures 1 to 4 show the variation of the subband quasi-particle weights $Z_i \approx 1/[1 - \text{Im} \Sigma_i(i\omega_0)/\omega_0]$ as functions of $U$ for various temperatures. Up to $T = 0.04$ eV the results show the typical hysteresis behavior obtained also for the single-band Hubbard model.\textsuperscript{7,17,18} If $U$ is gradually increased from the metallic side the transition occurs at a slightly larger critical value than if one begins in the insulating phase and gradually decreases $U$. The hysteresis is most pronounced at low temperatures and becomes weaker as $T$ increases. For $T \geq 0.05$ eV it is negligibly small and the transition begins to resemble the typical cross-over behavior.

The important point of these results is that the quasi-particle weights of the narrow and wide subbands exhibit first-order transitions at precisely the same critical $U_c(T)$. This picture supports our previous results suggesting a single Mott transition in a non-isotropic multi-orbital environment, in contrast to the orbital selective transitions found in Refs. 9 and 11. In line with the notation used in the single-band case, we denote the common critical value for decreasing $U$ as $U_{c1}(T)$ and for increasing $U$ as $U_{c2}(T)$. (These values should not be confused with the critical $U$ derived in Ref. 11 for the isotropic two-band models.) For $T \leq 0.04$ eV the transitions are perfectly discontinuous both at $U_{c1}(T)$ and $U_{c2}(T)$. For $T \geq 0.05$ eV finite temperature broadening progressively dominates the transition region.

Figure 5 shows the phase diagram obtained from the
functions \( Z_i(T, U) \). The overall shape of the phase boundaries agrees well with those obtained for the single-band Hubbard model. According to the single-band phase diagram, the actual first-order metal insulator transition takes place along an intermediate line \( U_c(T) \) such that \( U_{c1}(T) < U_c(T) < U_{c2}(T) \) (schematically indicated by the dashed curve). Extrapolation of the phase boundaries suggests a common transition temperature of about \( T_c \approx 0.05 \text{ eV} \). This value agrees well with the average between the critical temperatures derived for isotropic narrow and wide two-band systems, \( T_{c11} \approx 0.033 \text{ eV} \) and \( T_{c22} \approx 0.067 \text{ eV} \), respectively. In the single band case the IPT-DMFT yields \( T_c/W \approx 0.02 \). According to Eq.\( (3) \), for doubly degenerate bands and \( U = 2U' = 4J \), this value should be reduced by a factor \( (\sigma_1 + \sigma_2)^{1/2}/U \approx 1.2 \).

Although inter-orbital Coulomb interactions lead to a common metal insulator transition in the narrow and wide subbands, it is clear from Figs. 1 to 4 that the subband quasi-particle weights differ greatly both in the metallic and insulating phases. In this sense, the subband transitions are partly incomplete: On the metallic side, \( Z_1 \) is consistently smaller than \( Z_2 \) because of the more pronounced correlations within the narrow band. As a result, as will be discussed below, this band can exhibit quasi-insulating behavior. Conversely, on the insulating side of the transition, \( Z_1 \) drops almost to zero while \( Z_2 \) drops to a finite intermediate value and gradually decreases towards larger \( U \). This ‘bad-metal’ behavior of the wide band above the transition is weak at low temperatures but becomes more important towards \( T_c \). There is no indication of a second first-order transition in the wide subband at larger \( U \).

To analyze the subband quasi-particle properties close to the transition in more detail we show in Fig. 6 the self-energies \( \Sigma_i(i\omega_n) \) for \( T = 0.02 \text{ eV} \) near \( U_{c2}(T) \). Slightly below the transition at \( U = 2.91 \text{ eV} \) the wide band is clearly metallic with \( \Sigma_2(i\omega_n) \sim \omega_n \) at small Matsubara frequencies. The narrow band exhibits significant deviations from this linear behavior. Only at the two lowest frequencies \( \Sigma_1(i\omega_n) \) is roughly linear in \( \omega_n \). At larger frequencies it becomes inversely proportional to \( \omega_n \). Thus, this band is in the intermediate region between metallic and insulating behavior, exhibiting a narrow coherent peak near \( E_F \) nearly separated from pronounced Hubbard bands (see below). At \( U = 2.92 \text{ eV} \), i.e., just

![FIG. 4: Same as Fig. 1 except for (a) \( T = 0.05 \text{ eV} \) and (b) \( T = 0.1 \text{ eV} \). Hysteresis effects are negligible at these temperatures.](image)

![FIG. 5: Phase diagram for two-band Hubbard model, calculated within IPT-DMFT. Open dots: critical Coulomb energies \( U_{c1}(T) \) and \( U_{c2}(T) \) derived from Figs. 1 to 4. The lines are guides to the eye. Their extrapolation yields the common second-order critical point marked by a solid dot. The actual first-order line \( U_c(T) \) at low temperatures lies between \( U_{c1}(T) \) and \( U_{c2}(T) \) and is sketched by the dashed line.](image)

![FIG. 6: Self-energy \( \Sigma_i(i\omega_n) \) for two-band Hubbard model at \( T = 0.02 \text{ eV} \) near \( U_{c2}(T) \approx 2.91 \text{ eV} \) at small Matsubara frequencies. Solid (dashed) curves: narrow (wide) subband.](image)
above the transition, the narrow band has become fully insulating with $\Sigma_1(i\omega_n) \sim 1/\omega_n$. In contrast, $\Sigma_2(i\omega_n)$ approaches a constant in the limit of small $\omega_n$. Thus, the wide band still is in the intermediate range between metallic and insulating behavior. These results demonstrate that in the vicinity of the Mott transition the two subbands exhibit a complicated superposition of different cross-over behaviors as they switch between the metallic and insulating phases.

The effect of these subband dependent correlations on the quasi-particle spectra is illustrated in Fig. 7 for $T = 0.01$ eV just below and above $U_{c1}(T)$. On the metallic side, the wide band is perfectly metallic. The narrow band exhibits a very narrow coherent peak near $E_F$ and nearly vanishing weight between this peak and the large Hubbard peaks. Thus, the narrow band shows features indicative of both metallic and insulating behavior. Similarly, above the transition the coherent peak in $N_1(\omega)$ has vanished and a narrow excitation gap is visible. $N_2(\omega)$, on the other hand, still has appreciable spectral weight near the Fermi energy. According to the phase diagram, at sufficiently low temperatures the true first-order line $U_c(T)$ approaches the boundary $U_{c2}(T)$. In fact, within a consistent dynamical two-site approximation $U_c(T)$ is only slightly smaller than $U_{c2}(T)$. Fig. 1 shows that near this line the ‘bad-metal’ character of the wide subband above the transition is much weaker than close to $U_{c1}(T)$.

The above results suggest that, although there is a single metal insulator transition for both subbands, slightly below and above this transition the quasi-particle spectra are rather complicated, partially exhibiting ‘coexisting’ metallic and insulating behavior. In fact, in the range $0.01$ eV $\leq T \leq T_c$, the transition in the wide band might be more appropriately described as metal/bad-metal transition. However, this behavior is associated with the fact that at finite $T$ there is no clear distinction between metal and insulator. Extrapolation of the results shown in Figs. 1 to 4 to even lower temperatures suggests that the ‘bad-metal’ behavior in the wide band above $U_{c2}(T)$ eventually disappears and that the gaps in both bands open simultaneously at the same critical $U_c(T)$.

Before closing this section we briefly address the effect of the Hund’s rule exchange coupling on the correlations within the two-band Hubbard model. The relatively large value assumed so far, $J = U/4$, gives rise to considerable anisotropy and is partly the origin of the qualitative differences between the subbands, in particular near the transition. The reason for these differences can be understood in terms of the self-energy expression given in Eq. (3). For $J = U/4$: $\sigma_2/\sigma_1 \approx 0.5$ while for $J = 0$: $\sigma_2/\sigma_1 = 2$. Near the Fermi level the single-particle density of states scales with the band width, i.e., $g_1(\beta/2) = 2g_2(\beta/2)$ before the Coulomb interaction is switched on. Thus for $J = U/4$, $\tau = \beta/2$ one finds: $\Sigma_1/\Sigma_2 = (\sigma_1 g_1^2 + \sigma_2 g_1 g_2^2)/(\sigma_1 g_2^2 + \sigma_2 g_2 g_1^2) = (8 + 0.5 \times 2)/(1 + 0.5 \times 4) = 3$ whereas for $J = 0$: $\Sigma_1/\Sigma_2 \approx (8 + 2 \times 2)/(1 + 2 \times 4) = 4/3$. The subband contributions to the self-energy therefore differ significantly for $J = U/4$, but they are quite similar for $J = 0$, giving rise to much more isotropic behavior.

Fig. 8 shows the quasi-particle weights $Z_i$ as functions of $U$ for $J = 0$ at $T = 0.02$ eV. The compar-
ison with Fig. 2 demonstrates that as a result of the greater isotropy of the system the correlation induced reduction of quasi-particle weight is now quite similar for both subbands. In particular, slightly below and above the transition both bands show similar metallic and insulating behavior, respectively, in contrast to the much more complex superposition of quasi-metallic and -insulating behavior obtained for $J = U/4$. As before, both bands undergo a first-order metal insulator transition at the same critical $U$. Since there is neither single-particle hybridization nor Hund’s rule coupling between subbands, the common transition is entirely caused by the inter-orbital Coulomb interaction $U' = U$. Without this interaction, we would have $Z_1(U) \approx Z_2(2U)$ (slight differences arise as long as the temperature is held fixed). Thus, the critical Coulomb energies of the subbands would differ by the same factor as the band widths $W_i$. Fig. 8 shows that $U'$ enforces a single transition at an intermediate $U_c$. As in Fig. 2, the $Z_i$ exhibit similar hysteresis behavior: for decreasing $U$ the critical Coulomb energy is $U_{c1}(T) \approx 2.19$ eV while for increasing $U$ we find $U_{c2}(T) \approx 2.45$ eV.

III. QMC – DMFT

In our previous work\textsuperscript{[12]} we considered the same two-band Hubbard model as above with $W_2 = 2W_1 = 4$ eV. DMFT calculations based on the multi-band QMC method were performed for a rather high temperature, $T = 0.125$ eV, which corresponds to the cross-over region above the critical temperature $T_c$. For $J = 0.2$ eV, the quasi-particle weights $Z_i$ were found to differ significantly at intermediate Coulomb energies due to the different subband kinetic energy terms. Nevertheless, with increasing $U$ the $Z_i$ merge again and, within some uncertainty associated with critical slowing down, become very small at about the same $U_i(T)$.

Fig. 9 shows the quasi-particle weights $Z_i$ as functions of $U$ obtained from analogous QMC calculations for $J = U/4, U' = U/2$. In the cross-over region at high temperatures ($T = 0.125$ eV) the larger anisotropy caused by the stronger Hund’s rule coupling leads to a pronounced overall broadening of the transition region. This applies also to the isotropic two-band models with degenerate narrow or wide subbands. Nevertheless, in the anisotropic case (12) the $Z_i$ approach one another with increasing $U$ and exhibit qualitatively similar asymptotic behavior.

The results for $T = 0.031$ eV shown in Fig. 9(b) exhibit much sharper transitions in the isotropic as well as non-isotropic two-band systems. (In the single-band case\textsuperscript{[18]} $T_{c\text{QMC}}/T_{c\text{IPT}} \approx 0.75$. Assuming the same ratio for the two-band case we estimate from Fig. 5 for the non-isotropic model: $T_{c\text{QMC}} \approx 0.038$ eV.) In the non-isotropic case the overall behavior of the quasi-particle weights is remarkably similar to the IPT results discussed in the previous section. While $Z_1$ drops almost to zero near $U_{c2} = 2.1$ eV $Z_2$ drops to a finite value and then decreases gradually towards larger $U$. The characteristic kink in $Z_2$ becomes even more pronounced at $T = 0.02$ eV (see + symbols). This change in slope of $Z_2(U)$ near $U_{c2}$ suggests that both subbands undergo a common transition at the same Coulomb energy and that the wide subband exhibits pronounced ‘bad-metal’ behavior above $U_c$.

The hysteresis behavior of the $Z_i$ for $T = 0.02$ eV is
shown more detail in Fig. 9(c). While for increasing $U$ both $Z_i$ exhibit a change of slope near $U_{c2} \approx 2.1$ eV, for decreasing $U$ the common transition occurs at $U_{c1} \approx 1.8$ eV. (The vertical line of dots at 1.8 eV indicates the iterations from the lower to the upper branch.) As in the case of the IPT, there is no evidence for a second transition in the wide subband at larger $U$.

As can be seen in Fig. 10, the self-energies $\Sigma_i(i\omega_n)$ close to the critical Coulomb energy derived within the QMC method are consistent with those obtained in the IPT (see Fig. 6). At $U \leq 2.4$ eV the wide band is in the cross-over region between metallic and insulating behavior. For $U = 2.7$ eV $\Sigma_2(i\omega_n)$ becomes inversely proportional to $\omega_n$, i.e., a gap opens up. The narrow band undergoes a similar cross-over behavior, except at slightly lower values of $U$.

Fig. 11 shows the quasi-particle spectra for $T = 0.031$ eV in the vicinity of the critical Coulomb energy. When the narrow band is about to open a gap, the wide band is still fairly metallic. Its own gap would be even smaller and is therefore readily filled by finite temperature tails extending from the Hubbard peaks towards the Fermi level. Only if $U$ is increased to about 2.7 eV is the gap in the wide band large enough to not be obliterated by this temperature broadening.

The variation of $Z_i(U)$ with increasing $U$ shown in Fig. 9(b) is qualitatively similar to the one obtained by Koga et al. within the exact diagonalization treatment of the non-isotropic two-band model: Near $U_c \approx 2.6$ eV $Z_1$ practically vanishes while $Z_2(U)$ remains finite but shows a characteristic change in slope. At larger Coulomb energies $Z_2$ decreases gradually without any clear evidence for a subsequent metal insulator transition. ($U_c$ is somewhat larger than in our QMC results since the ED calculations are carried out at near zero temperature. According to the phase diagram shown in Fig. 5 $U_{c2}(T)$ increases slightly with decreasing $T$.)

Since the ED-DMFT results are basically similar to our QMC-DMFT calculations, the different conclusions reached in Refs. 11 and 13 seem to stem primarily from different interpretations of the underlying physics: In our view there is only one first-order transition, but with complex quasi-metallic and -insulating subband features just below and above this transition. This picture is based on the simultaneous discontinuous changes of the subband quasi-particle weights derived within the IPT-DMFT and the consistency between the IPT and QMC results. On the other hand, if the vanishing of the $Z_i$ is used as a criterion, the subbands indeed behave very differently. Whereas for the narrow band a critical Coulomb energy can readily be identified, $Z_2$ falls off gradually and becomes negligibly small at much higher values of $U$. This metallic ‘tail’ of $Z_2$ makes it difficult to identify a second critical Coulomb energy. According to our QMC and IPT results, this metallic tail should diminish at low
temperature. It is not clear at present why the ED results in Ref. 13 show such a tail although they apply to near zero temperature. Also, it is not clear to what extent the different subband $U_c$’s obtained within the two-site DMFT depend on the minimal one-level representation of the subband baths. The energy discretization inherent in both the ED and two-site methods plays a crucial role close to the transition when dynamical correlation effects on small energy scales are particularly important. It would be interesting to perform ED and 2-site DMFT calculations in a wider range of temperatures in order to analyze the transition region in more detail.

IV. SUMMARY

The nature of the Mott transition in multi-band systems was investigated within the dynamical mean field theory. Although in practice subbands of transition metal oxides are usually coupled via single- as well as many-electron interactions, we focus here on the effect of inter-orbital matrix elements of the Coulomb energy, thus neglecting one-electron hybridization. In contrast to isotropic systems consisting of identical subbands, the metal insulator transition in materials with coexisting narrow and wide subbands turns out to be remarkably complex. The present results confirm our previous finding, namely, the existence of a single transition rather than a sequence of orbital-selective transitions as the on-site Coulomb energy is increased. Nevertheless, at low but finite temperatures below the transition the narrow band reveals a narrow coherent peak nearly separated from the Hubbard bands. Conversely, above the transition the wide band shows pronounced bad-metal behavior. This coexistence of quasi-metallic and -insulating spectral features in the vicinity of the transition makes the interpretation of the DMFT results non-trivial and partly explains the contradictory findings in Refs. 11 and 13.

Since it is difficult to perform QMC calculations at very low temperatures, we have carried out extensive DMFT calculations within the IPT. The phase diagram is consistent with earlier results obtained for single-band models. In particular, the quasi-particle weights show the typical hysteresis behavior giving rise to two first-order lines $U_{c1}(T)$ and $U_{c2}(T)$ defining the stability boundaries of the insulating and metallic regions, respectively. For $T \leq 0.01 \text{ eV}$ the results suggest that above the transition the metallic states in the wide band should disappear, i.e., that the excitation gaps in both bands should open at the same $U_c(T)$. At intermediate temperatures below $T_c$ the IPT results are consistent with the QMC calculations: The quasi-particle weights in both subbands undergo simultaneous first-order transitions at $U_{c1}(T)$ or $U_{c2}(T)$. These transitions, however, are not complete in one or the other of the subbands. For instance, the wide band shows appreciable metallicity above the transition. Similarly, the narrow band exhibits partly insulating Hubbard peaks below the transition. This mixture of metallic and insulating behavior diminishes towards low temperatures, i.e., purely metallic or insulating phases should evolve in both subbands.

I like to thank A. Bringer for useful discussions. I also thank V. Oudovenko for sharing his subroutines for imaginary time/frequency Fourier transforms.
