Abstract

The northern bobwhite (Colinus virginianus) is an ecologically and economically important avian species. At the present time, little is known about the microbial communities associated with these birds. As the first step to create a quail microbiology knowledge base, the current study conducted an inventory of cultivable quail tracheal, crop, cecal, and cloacal microbiota and associated antimicrobial resistance using a combined bacteriology and DNA sequencing approach. A total of 414 morphologically unique bacterial colonies were selected from nonselective aerobic and anaerobic cultures, as well as selective and enrichment cultures. Analysis of the first 500-bp 16S rRNA gene sequences in conjunction with biochemical identifications revealed 190 non-redundant species-level taxonomic units, representing 160 known bacterial species and 30 novel species. The bacterial species were classified into 4 phyla, 14 orders, 37 families, and 59 or more genera. *Firmicutes* was the most commonly encountered phylum (57%) followed by *Actinobacteria* (24%), *Proteobacteria* (17%) and *Bacteroidetes* (0.02%). Extensive diversity in the species composition of quail microbiota was observed among individual birds and anatomical locations. Quail microbiota harbored several opportunistic pathogens, such as *E. coli* and *Ps. aeruginosa*, as well as human commensal organisms, including *Neisseria* species. Phenotypic characterization of selected bacterial species demonstrated a high prevalence of resistance to the following classes of antimicrobials: phenicol, macrolide, lincosamide, quinolone, and sulphate. Data from the current investigation warrant further investigation on the source, transmission, pathology, and control of antimicrobial resistance in wild quail populations.

Introduction

The northern bobwhite (*Colinus virginianus*) is an ecologically and economically important natural resource in the United States. A survey conducted by the U.S. Fish and Wildlife Service in 2011 indicates that bobwhite is one of the most preferred small game species pursued by over 840,000 hunters on over 9 million hunting days in 2011 [1]. Over the past several decades, bobwhite populations have been declining across their range. In the state of Texas alone, bobwhites have been diminishing at an average annual rate of 5.6% since 1980 which has resulted in a 75% population decline [2]. Although habitat loss associated with intensive agricultural practices has been considered as a major contributor, quail declines have continued even in areas of apparently suitable habitat during favorable weather conditions [3]. The involvement of infectious agents has been investigated, but studies have failed to identify any pathogens with the potential to kill large numbers of quail [4], [5]. This ongoing decline, termed “Idiopathic Quail Decline” underscores the need for a holistic approach to the study of quail health [3], [6].

One important aspect of animal health that is just beginning to be understood among many vertebrate species is the indigenous microbial populations or the microbiota. Recent investigations have shown that the host’s nutritional, physiological, and immunological processes are profoundly affected by the microbiota [7], [8], [9]. However, the composition of the microbiota is also influenced by factors such as the host’s genetics, diet, environment, and infection status [7], [9]. The gut microbiota contributes to the digestion and fermentation of carbohydrates, the development of gut-associated lymphoid tissues (GALTs), and the prevention of colonization by pathogens [10].

Over the past two decades, numerous culture-dependent and culture-independent microbiome studies have been carried out to characterize the composition and dynamic changes of intestinal microbiota of mammals, domestic poultry, and several wild avian species [11], [12], [13], [14], [15]. However, the microbiota of northern bobwhite remains largely unexplored. Documenting the microbiota of this species is important because it may identify agents that could contribute to the ongoing population declines. In addition, it is important to document the presence and extent of
antimicrobial resistance in bobwhite bacterial microbiota because wild birds could carry drug resistant bacteria potentially pathogenic to humans and other animal species [16, 17]. Although wild bobwhite populations do not have contact with antibiotics as therapeutic agents, exposure via water and food contaminated by antimicrobial resistant bacteria originating from human waste or farm-reared quail is likely [10, 19, 20]. Previously, multidrug resistant Salmonella enterica serovar Typhimurium was isolated from diseased bobwhites [21]. Resistance to tetracycline was detected in Edwardsiella hoshinae isolated from healthy northern bobwhite quail [22]. However, no study has been conducted to determine the susceptibility or resistance patterns of other bacterial species commonly found in avian and mammalian gastrointestinal tracts. If bobwhites do carry drug-resistant organisms as part of their microbiota, they may serve as a reservoir for antimicrobial resistant bacteria or resistance genes that can be transmitted to other wild animals or to humans upon handling and consumption.

To fill the gaps in existing knowledge relating to bobwhite microbiology, the current investigation characterized cultivable tracheal and gastrointestinal microbiota of wild northern bobwhite and determined the antimicrobial susceptibility and resistance patterns of selected commensal and opportunistic pathogenic bacterial species.

Materials and Methods

Sample Collection and Processing

Sample collection and processing were completed by the Central Specimen Receiving, Processing and Distribution Laboratory (CSRPDL) of the Institute of Environmental and Human Health, Texas Tech University. Animal and tissue uses were approved by the Institutional Animal Care and Use Committees of Texas A&M University (IACUC 2011-193) and Texas Tech University (IACUC 11049-07). A total of 49 live-trapped bobwhites throughout the Rolling Plains Ecoregion were used in this study. Due to sample sharing among multiple investigators, only 49 trachea, 48 crops, 39 ceca, and 38 cloacal swabs were available for microbiological evaluations. All trapping practices were conducted under the auspices of a Texas Parks & Wildlife Department Scientific Collector’s permit. Each bird was labeled with a unique 6-digit ID number while the sex and age were determined by trained personnel using plumage characteristics. The age of three birds was not labeled due to unknown reasons. Tissue and swab samples in Cary-Blair transport medium (BD, Franklin Lakes, NJ, USA) were transported from the field on ice to CSRPDL within 8 hours. All samples were stored at −20°C until testing (within 2 months). Prior to culture, trachea, crops, and ceca were thawed and cut open aseptically.

Cultivation of Bacteria

The luminal contents and/or mucosal surfaces of trachea, crops, and ceca were sampled with sterile polyester swabs (Puritan Medical, Guilford, Maine, USA). Tracheal samples were inoculated onto the surface of solid media including Tryptic Soy Agar with 5% Sheep Blood (TSA), Columbia Colistin Nalidixic Acid agar with 5% Sheep Blood (CNA), Anaerobic Phenethyl Alcohol Blood agar (PEA), MacConkey agar (MAC), and Lowenstein-Jensen Medium Slants (LJ); and into Brain Heart Infusion broth (BHI) and Mycoplasma broth (Frey). Crop, cecal, and cloacal samples were inoculated onto TSA, CNA, PEA, MAC, and Xylose-lysine-tergitol 4 (XLT4) as well in Brain Heart Infusion broth (BHI) and Buffered Peptone Water (BPW). Aerobic cultures (TSA, CNA, LJ, BHI, and Frey) were incubated at 37°C in anaerobic jars with disposable gas packs (Remel Inc., Lenexa, Kansas, USA). Cultures (TSA, CNA, MAC, PEA, XLT4) were examined daily for growth up to 5 days. Mycoplasma cultures (Frey) and mycobacteria cultures (LJ) were incubated for 14 days. BHI and BPW cultures were subcultured after overnight incubation onto TSA and XLT4, respectively. Morphologically unique bacterial colonies were subcultured under appropriate conditions to obtain pure cultures.

Bacterial Identification and Antimicrobial Susceptibility Testing

Partial characterization of bacterial strains was also performed by biochemical tests, including Gram staining, production of oxidase, catalase, urease, motility, and indole test. Selected biochemical reactions from several bacterial ID kits, including RapID CB Plus, RapID ANA II, RapID NF Plus, RapID One, RapID Staph, and RapID STR, were also used to confirm identity. Pure bacterial cultures were subjected to 16S rDNA gene sequencing. To prepare DNA template for PCR, isolated colonies (1 to 2) were resuspended in 100 µl of ddH2O and boiled for 10 min. The bacterial broad-range 16S rDNA primer pairs: f1-lmd (5’-AGAGTTTGATCTGCTGGAGYAG-3’) corresponding to positions 8–27 in the E. coli 16S rDNA gene and 16S1RR-B (5’-CITTTACGCGGARRAWTCCG-3’, corresponding to positions of 556–575) [23] were used to amplify the 16S rDNA gene. The thermal cycling conditions were as follows: an initial denaturation at 94°C for 3 min; 35 cycles of 94°C for 30 sec, 56°C for 30 sec, and 72°C for 30 sec; and a final extension step at 72°C for 7 min. A portion of each PCR product was subjected to electrophoresis on 1.5% agarose gel and visualized using the AlphaImager Gel Documentation system (ProteinSimple, Santa Clara, CA). The PCR products were purified and sequenced using the 16S1RR-B primer. The resultant sequences were subjected to homology search against GenBank database by using the BLAST search algorithm as well as MicroSeq ID 2.0 500-hp library (Applied Biosystems, Foster, CA). Sequence identities of ≥99% and ≥97% were used as criteria for species and genus assignments, respectively. The sequences sharing less than 97% identities with the 16S rDNA sequences in the databases were considered as potentially new species [24].

Selected bacterial species were subjected to antimicrobial susceptibility testing using the Sensitiser Veterinary Susceptibility Plates, AVIAN1F, (Trek Diagnostic Systems, Westlake, OH); the inoculated antimicrobial plates were incubated at 37°C in ambient air for 24 h. The antimicrobial agents tested included amoxicillin, cefiufor, clindamycin, enrofloxacin, erythromycin, florfenicol, gentamicin, neomycin, novobiocin, oxytetracycline, penicillin, spectinomycin, streptomycin, sulphadimethoxine, sulphatiazole, tetracycline, trimethoprim/sulpha, and tylosin. The results were interpreted by using Clinical Laboratory Standards Institute (CLSI) guidelines for broth microdilution methods [25]. E. coli ATCC 25922 and Ps. aeruginosa ATCC 27853 were used as the quality control strains.

Statistical Analysis

To determine if the number of bacterial species found in each sample varied with regard to sex, age, tissue type or sex by age interaction we used a general linear model with a Poisson distribution. To determine if the distribution of bacterial species varied with tissue type, age and the sex by age interaction term we used a binomial logistic regression for all bacterial species which were detected in 15 or more different tissues. Binomial logistic regression was used to determine if the distribution of

PLOS ONE | www.plosone.org 2 June 2014 | Volume 9 | Issue 6 | e99826
bacterial genera varied by tissue type, sex, age and the sex by age interaction for all genera which were detected in 15 or more tissue samples analyzed. These analyses included data from 45 healthy bobwhites for which age class and sex were known. Data from one Scaled Quail (*Callipepla squamata*) and one sick Northern Bobwhite were omitted along with data from two birds for which age class was unknown and one for which age, sex and species were unknown. For all analyses we used an \( \alpha = 0.05 \).

Bacterial Species Unique to Individual Birds

Figure 1. The number of bacterial species and the species diversity of northern bobwhite cultivable bacterial microbiota. 1A. Species data from 28 individual quail for which all four tissue types are presented. Cultures of most quail yielded 16 to 20 bacterial species while the cultures of a moribund quail gave rise to 26 bacterial species. 1B. Data presented are percentage of unique bacterial species (total number = 190) found in individual quail. Vast majority of bacterial species were unique to individual quail. doi:10.1371/journal.pone.0099826.g001

rRNA gene sequences deposited in GenBank, therefore representing known bacterial species. In addition, 9 (4.74%) sequences showed 97% to 98% similarities and 21 (11%) sequences had less than 97% of similarities to previously reported 16S rRNA gene sequences, suggesting that these were novel species and genera (Table S1). The sequences of all species level taxa have been submitted to GenBank.

The quail bacterial species could be classified into 4 phyla, 14 orders, 38 families, 61 genera, and 160 known species and potentially 30 novel species (Table 1). Firmicutes (56%) was the largest phylum, followed by Actinobacteria (24%), Proteobacteria (18%) and Bacteroidetes (0.02%). At family level, the vast majority of bacterial species belonged to Bacteroidaceae (22%), Paenibacillaceae (11%), Enterobacteriaceae (11%), Microbacteriaceae (6.84%), Lactobacillaceae (5.79%), and Streptococcaceae (5.79%).

Composition of Tissue-specific Cultivable Bacterial Microbiota

The tracheal microbiota consisted of 21 species belonging to 12 families with Lactobacillaceae (19%) being the most commonly encountered bacterial family. The crop microbiota consisted of 90 species from 22 families with Bacillaceae (21%) and Enterobacteriaceae (18%) being the top 2 families. The cecal microbiota consisted of 69 species from 22 families with Bacillaceae (29%), Enterococcaceae (10%), and Paenibacillaceae (10%) being the top 3 families. The cloacal microbiota was composed of 71 species belonging to 19 families with Bacillaceae (28%) and Streptococcaceae (13%) being the majority (Table 2).

Influence of Age, Sex, and Tissue Type on Quail Cultivable Bacterial Microbiota

Significant differences in the distribution of bacterial taxa among age, sex, and tissue groups were detected. At the genus level, the regression models explained between 16% and 57% of the variation in the distribution of the eight most common bacterial genera (Table 3). Of these eight genera, only three differed significantly between males and females (Binomial Logistic Regression, Table 3). Enterococcus was more common than expected in females (p = 0.013) and Rothia and Streptococcus were more common than expected in males (p = 0.024 and 0.036, respectively). Only Paenibacillus differed between age classes: it was more common than expected in juveniles (p = 0.05, Table 3). For Cronobacter the sex by age interaction term was significant: this genus was much less common than expected in adult females and slightly more common than expected in adult males (p = 0.04, Table 3). At species level, Enterococcus faecium was more common in females than males (p = 0.043) and Rothia nasimurium was more common in males than females (p = 0.026).

Most variations in quail microbiota were driven by tissue types or anatomical locations. Compared to intestinal microbiota, tracheal microbiota was less diverse, as evidenced by the low number of taxa found in tracheal samples. All of the 8 most common bacterial genera differed significantly among tissue types (P<0.0002 for all). Cronobacter, Rothia, and Streptomyces were most common in crop while Enterococcus, Lactobacillus and Paenibacillus were most common in cecum. Streptococcus and Bacillus were fairly common in all three sections of the GI tract but were very rare or absent from the trachea.

Bacterial Species Diversity of Quail Cultivable Bacterial Microbiota

Data for 28 quail for which all four tissue types were available for culture were analyzed and presented in Fig. 1A. The number of bacterial taxa found per tissue analyzed did not differ significantly by sex, age or the interaction between sex and age, but did differ significantly by the type of tissue analyzed (GLM Poisson distribution: Overall ChiSquare = 126, DF = 6, P<0.0001, P values for sex, age and sex*age >0.1, P value for tissue type <0.0001). Cultures of most quail yielded 16 to 20 bacterial species per bird. The cultures of a moribund juvenile bird yielded 26 bacterial species (Fig. 1A). Extensive variation in the composition of quail microbiota was observed among individual birds (Fig. 1B). Approximately 48% of bacterial species were unique to individual birds; 17%, 8%, 5%, and 4% of bacterial...
### Table 3. Influence of age, sex and tissue type on the distribution of microbial taxa*.

| Family        | # of Taxa | P     | R²    | M | F | Sex-P | A | J | Age-P | Tr | Cr | Ce | Cl | Tissue-p |

*Shown are the numbers (percentages) of quail and tissue tested positive.

doi:10.1371/journal.pone.0099826.t004
species were found in 2, 3, 4, and 5 birds, respectively (Fig. 1B). In general, less than 3% of bacterial species could be found in more than 7 quail.

At the tissue level, samples from the cecum had the highest number of bacterial species (6.25 ± 2.89, N = 36 analyzed) followed by crop (6.4 ± 2.78, N = 43), cloaca (4.0 ± 0.267, N = 29) and trachea (1.36 ± 0.74, N = 14). Means from all four tissue types differed significantly (Least Squares Means Student’s t test, p < 0.05). Eighty one percent of tracheal bacterial species were unique to individual tissue samples; and only 10% and 5% were found in 2 and 3 tissues, respectively (Fig. 2A). About 53% of crop bacterial species were unique to individual samples and less than 4% of bacterial species were found in 4 or more samples (Figure 2B). Compared to crop microbiota, less diversity was associated with cecal microbiota. About 41% of cecal bacterial species were unique to individual samples and less than 4% of bacterial species were found in 4 or more samples (Figure 2C).

Cross-tissue analysis of microbiota showed that 48% of tracheal species were found in the intestine (Fig. 3). These species included Acinetobacter baumannii, Bacillus aryabhattai, Bacillus subtilis, Enterococcus faecium, Klebsiella oxytoca, Lactobacillus agilis, Lactobacillus salivarius, Lactobacillus gasseri, Microbacterium testaceum, and Pseudomonas aeruginos. Variation throughout the intestinal tract was detected. Only 8 bacterial species (4.47%) were consistently cultured from crops, ceca, and cloaca (Figure 3). The common species of intestinal microbiota included Bacillus cereus, Bacillus megaterium, Bacillus nelsoni, Bacillus pumilus, Bacillus simplex, Bacillus subtilis, Enterococcus faecium, and Staphylococcus gallinarum. Bacillus subtilis and Enterococcus faecium were the common species found in all tissue specific microbiota.

Pathogenic and Opportunistic Pathogenic Bacterial Species

Mycobacterium sp., possibly a member of the M. terrae complex, was isolated from the trachea of one bird. Pseudomonas aeruginos was identified from 12 (24%) birds, including 8 tracheae, 2 crops, and 3 ceca. E. coli was cultured from 16 (32%) quail, including 1 crop and 15 ceca (Table 4). In addition, several species usually considered as human commensal organisms, including Neisseria
flavescens (6%) and Neisseria sicca (6%) were cultured from the ceca and cloaca of quail (Table 4).

### Table 5. Antimicrobial susceptibility pattern of Gram negative bacteria isolated from bobwhites*

| Antimicrobial Agents | E. coli (n = 16) | Enterobacter sp (n = 13) | Neisseria sp. (n = 5) | Ps. aeruginosa (n = 13) |
|---------------------|------------------|--------------------------|-----------------------|-------------------------|
| Beta-lactam         |                  |                          |                       |                         |
| Amoxicillin         | 4–8 (100)        | 2–8 (31), ≥16 (69)       | 0.25–0.5 (100)        | ≥16 (100)               |

Antimicrobial Resistance of Quail Cultivable Bacterial Microbiota

Phenotypic analysis of quail bacterial isolates revealed varying degrees of resistance to multiple classes of antimicrobials (Table 5).
Table 6. Antimicrobial susceptibility pattern of Gram positive bacteria isolated from bobwhites*.

| Antimicrobial | B. subtilis (n = 10) | E. faecalis (n = 10) | S. gallinarum (n = 10) |

|                | Trimethoprim/Sulpha  | ≤0.5 (100)           | ≤0.5 (100)             |

*The ranges of MICs (% of isolates) are indicated as follows: regular font, susceptible; bold and italic, intermediate susceptible; and bold and underlined, resistant.

doi:10.1371/journal.pone.0099826.t006

and 6). Resistance to penicillin, clindamycin, erythromycin, and sulphadimethoxine was detected in all E. coli (100%) isolates (n = 16). Resistance to florfenicol and sulphatiazole were found in 75% and 25% of isolates, respectively (Table 5). Intermediate susceptibility to spectinomycin, florfenicol and sulphatiazole was shown by 100%, 75%, and 25% of isolates, respectively (Table 5). Intermediate susceptibility to spectinomycin, florfenicol and sulphatiazole was found in vast majority of E. coli isolates, respectively. Similar resistance patterns were detected in Enterobacter and Neisseria isolates except that most Enterobacter isolates were also resistant to amoxicillin and Neisseria isolates were susceptible to florfenicol. Resistance to 15 of the 18 antimicrobials tested was detected in vast majority of P. aeruginosa isolates (Table 5). Intermediate susceptibility to oxytetracycline was found in 54% of the isolates. Gentamicin and Neomycin were the only 2 antimicrobials effective against all P. aeruginosa isolates. Antimicrobial resistance was also detected in Gram positive bacteria (Table 6). Most E. faecalis isolates were resistant to cefotiofur, streptomycin, clindamycin, sulphadimethoxine, and sulphatiazole. Intermediate susceptibility to spectinomycin and enrofloxacin was detected in E. faecalis isolates. B. subtilis and S. gallinarum were less resistant than E. faecalis to several antimicrobials tested.

Discussion

The present study provides the first inventory of cultivable bacterial microbiota of northern bobwhite. Using traditional microbiological cultures, biochemical testing, and 16S rDNA sequencing, we cultured and identified a large number of quail bacteria to species level. In total, we obtained 190 bacterial species with 21, 90, 69, and 71 species from the trachea, crop, ceca, and cloaca, respectively. The species coverage was greater than what were achieved in previous studies using culture-independent technique to characterize the cloacal microbiome of parrot (49 operational taxonomic units, OTU’s) or wild black-legged kitiwakes (64 OTUs) [15], [26]. However, culture-dependent approach made it less possible for in-depth quantitative analysis of species abundance and most likely failed to capture many bacterial species that cannot be cultured in the lab. Nonetheless, a collection of diverse live cultures made it possible for phenotypic characterization of microbes of interest.

Similar to the microbiota of other wild avian species, the microbial community of quail consists primarily of 4 phyla, including Firmicutes, Actinobacteria, Proteobacteria, and Bacteroidetes [15], [26], [27], [28]. Although both Firmicutes and Bacteroidetes are predominant phyla in the microbiome of mammals or domestic poultry, Bacteroidetes were rarely detected in the current study or previous studies dealing with certain bird species, such as gull and parrots [15], [26], [27]. The members of Bacteroidetes are known for their ability to degrade carbohydrates which are readily available to granivores, including bobwhites. This could be a result of technical limitations, such as sample storage, shipment, culture media not optimized or wild quail specimens, because we did experience difficulties in maintaining the viability of certain obligate anaerobic isolates which could affect the final results. In this study, we detected a relative richness in Actinobacteria and Bacillus which may be associated with the ground-dwelling life style of bobwhites that are in close contact with many soil bacteria. These bacterial species in quail gut may help to digest cellulose in quail diet, such as greens and fibrous seeds (e.g., Russian thistle, Salsola kali).
been demonstrated to be inhibitors of pathogenic bacteria of animals, such as Campylobacter jejuni and Clostridium botulinum [31], [32]. The antimicrobial property of Pseudomonas may be utilized to promote quail gut health as being done in chickens [31]. In addition to age, sex was another factor that influenced the distribution of two closely related genera, namely Enterococcus and Streptococcus. In addition, we observed that the vast majority of bacterial species were unique to individual birds and only a small percentage of bacterial species could be found in multiple birds. Variation in bacterial species composition was also detected among tissues with only eight species being conserved throughout the intestinal tract. In this study, the experimental quail were collected from multiple ranches across the Rolling Plains ecoregion which may contribute to this high degree of variation among individual quail.

We performed several types of selective and enrichment cultures to capture pathogenic bacteria that have fastidious growth requirements. However, our results show an extremely low prevalence of traditionally known respiratory and enteric pathogens in bobwhite populations. Except the Mycobacterium species isolated from one bird, no other obligate and zoonotic agents were cultured from bobwhite. The low prevalence could be associated with technical limitations such as media and culture conditions were not optimized for wild quail specimens. Instead, we isolated several opportunistic pathogens, such as E. coli, Enterobacter spp., and Ps. aeruginosa. In general, E. coli is not considered part of the intestinal flora of granivorous birds and its prevalence is much higher in farm-reared and restocked birds than wild populations [33], [34]. Ps. aeruginosa is known as an environmental organism and airway colonization by Ps. aeruginosa can contribute to local inflammation and respiratory disorder [35], [36]. Additionally, bobwhite cloacal microbiota harbored several species that are usually considered human commensal organisms, including Neisseria species and Streptococcus mitis. Whether these are indigenous quail bacteria or contaminants due to human activities remains to be determined.

Antimicrobial resistance is an important issue to both wildlife conservation and public health [37]. The prevalence of antimicrobial resistance in wildlife is often unknown or underestimated. This is because many resistant bacteria are components of indigenous bacterial flora and routine diagnostic and surveillance programs do not target these organisms. In the present study, we detected a strikingly high rate of antimicrobial resistance in quail microbiota. Nearly all E. coli, Enterobacter, and Neisseria isolates were resistant to following classes of antibiotics: phenicol, macrolide, lincosamide, quinolone, and sulphate. Either intermediate susceptibility or resistance to beta-lactams and aminoglycosides were also found in these Gram negative bacterial isolates. The Gram positive bacteria, E. faecalis and Staphylococcus isolates, were resistant to beta-lactam and sulphate antibiotics, in addition to aminoglycosides. All Ps. aeruginosa appeared to be more resistant than environmental isolates as previously reported [37]. Wild bobwhites are not subjected to the selective pressure associated with the use of antibiotics. However, habitat pollution and the release of farm-reared bobwhites could introduce resistant organisms or resistance genes into wild quail populations. Currently, erythromycin, neomycin sulfate, penicillin G, chlorotetracycline, lincomycin, spectinomycin are readily available to quail farms for prophylactic or therapeutic use. Although the exact source of antimicrobial resistance in wild quail populations remains to be investigated, human exposure to quail antimicrobial resistant microbiota should not be neglected.

In conclusion, the present study characterized the cultivable bacterial microbiota of northern bobwhite. We isolated multiple Pseudomonas spp. that are known to be inhibitors of pathogenic bacteria. We also obtained multiple isolates potentially representing new bacterial taxa whose complete characterization is currently underway. Overall, the prevalence of pathogenic bacteria in bobwhite populations is low. However, phenotypic characterization of selected bacterial species revealed a high prevalence of resistance to multiple classes of antimicrobial agents commonly used in avian medicine. The extent of antimicrobial resistance in quail microbiota warrants further investigation on the transmission of antibiotic resistance between wild and domestic quail populations and between bobwhites and humans.

Supporting Information

Table S1 Bacterial species isolated from Bobwhite quail. The 16S rRNA Gene Sequences (~500 bp) were subjected to homology search against GenBank database by using the BLAST search algorithm as well as MicroSeq ID 2.0 500-bp library. Accession number of the best match and percent of similarity are provided. Tissue type: Ce, cecum, Cr, crop; Cl: cloaca; and Tr: trachea. (DOCX)
