Abstract

Background: In experimental models, hypothalamic inflammation is an early and determining factor in the installation and progression of obesity. Pharmacological and gene-based approaches have proven efficient in restraining inflammation and correcting the obese phenotypes. However, the role of nutrients in the modulation of hypothalamic inflammation is unknown.

Methodology/Principal Findings: Here we show that, in a mouse model of diet-induced obesity, partial substitution of the fatty acid component of the diet by flax seed oil (rich in C18:3) or olive oil (rich in C18:1) corrects hypothalamic inflammation, hypothalamic and whole body insulin resistance, and body adiposity. In addition, upon icv injection in obese rats, both o3 and o9 pure fatty acids reduce spontaneous food intake and body mass gain. These effects are accompanied by the reversal of functional and molecular hypothalamic resistance to leptin/insulin and increased POMC and CART expressions. In addition, both, o3 and o9 fatty acids inhibit the AMPK/ACC pathway and increase CPT1 and SCD1 expression in the hypothalamus. Finally, acute hypothalamic injection of o3 and o9 fatty acids activate signal transduction through the recently identified GPR120 unsaturated fatty acid receptor.

Conclusions/Significance: Unsaturated fatty acids can act either as nutrients or directly in the hypothalamus, reverting diet-induced inflammation and reducing body adiposity. These data show that, in addition to pharmacological and genetic approaches, nutrients can also be attractive candidates for controlling hypothalamic inflammation in obesity.
**Materials and Methods**

**Experimental animals**

Rats and mice were obtained from the University of Campinas Breeding Center. Male Wistar rats (*Rattus norvegicus*) with an initial body mass of 180 g, were allowed access to standard rodent chow (CT) or high-fat diet (HF), according to a protocol described below and in Table 1. Male Swiss mice (*Mus musculus*) with an initial body mass of 13 g, were allowed access to standard rodent chow (CT), high-fat diet (HF), HF + flax seed oil (FS) (stepwise substitutions corresponding to 10, 20 or 30% of total caloric value) or HF + olive oil (OL) (stepwise substitutions corresponding to 10, 20 or 30% of total caloric value), as described below and in Table 1. All animals received diet and water *ad libitum* and were maintained in individual cages at 21±2°C, with a 12-h dark/12-h light cycle. All experiments were conducted in accordance with the principles and procedures described by the National Institutes of Health Guidelines for the Care and Use of Experimental Animals and were approved by the University of Campinas Ethical Committee (ID 2010/0256).

**Experimental protocols**

Experimental animals were submitted to two distinct approaches to evaluate the role of unsaturated fatty acids in hypothalamic dysfunction. Swiss mice (Fig. 1A), fed for 8 weeks on a HF diet, were randomly assigned to one of the following regimens: maintained in amber bottles and stored at 22°C. The diets were prepared every ten days and kept protected from light, at 4°C. The diets were analyzed with a N-EVOLUTE Plus 3000 analyzer (Thermo Scientific, Waltham, MA, USA) and were stored at −80°C until use.

**Antibodies, chemicals and buffers**

The reagents for SDS-polyacrylamide gel electrophoresis and immunoblotting were from Bio-Rad (Richmond, CA, USA). HEPES, phenylmethylsulfonyl fluoride, aprotinin, dithiothreitol, Triton X-100, Tween 20, glycerol, oleic acid/C18:1/α/ω (O-1303–1G), linolenic acid/C18:3/α/ω (L-2376), stearic acid/C18:0 (L-5376), bovine serum albumin (fraction V) and bovine serum albumin fatty acid free (A-6003), were purchased from Sigma-Aldrich (St. Louis, MO, USA). The reagents for chemoluminescence labeling of proteins in blots were from Amersham (Aylesbury, UK). Human recombinant insulin (Humulin R) and sodium thiopental were from Lilly (Indianapolis, IN, USA). Anti-Ak (sc-1618, goat polyclonal), anti-phospho Ser473 Akt (sc-7985-R, rabbit polyclonal), anti-FoxO1 (sc-1350, rabbit polyclonal), anti-phospho [Ser256] FOXO1 (sc-7977, rabbit polyclonal), anti-phospho [Tyr1007/1008] JAK2 (rabbit polyclonal), anti-JAK2 (sc-7977, rabbit polyclonal), anti-FOXO1 (sc-1350, rabbit polyclonal), anti-phospho [Ser256] FOXO1 (sc-22158-R, rabbit polyclonal), anti-phospho [Tyr1007/1008] JAK2 (rabbit polyclonal) anti-FOXO1 (sc-1350, rabbit polyclonal), anti-FOXO1 (sc-7977, rabbit polyclonal), anti-IL-6 (sc-1265, goat polyclonal), anti-IL-10 (sc-1783, goat polyclonal), anti-IF-β/β (sc-25830, rabbit polyclonal), anti-tubulin (sc-7977, rabbit polyclonal).

anti-IkB-α (sc-1643, mouse monoclonal), anti-phospho [Thr 183/185] c-Jun N terminal kinase (JNK) (sc-12882, rabbit polyclonal), anti-IKK (sc-1648, mouse monoclonal), anti-stearoil CoA desaturase-1 (SCD-1) (sc-23016, rabbit polyclonal), anti-carnitine palmitoyl transferase 1 (CPT1) (sc-20514, goat polyclonal), anti-fatty acid-1 (SCD-1) (sc-23016, rabbit polyclonal), anti-caspase 3 (sc-7148, rabbit polyclonal), anti-Bcl2 (sc-783, rabbit polyclonal), anti-Bax (sc-3225, rabbit polyclonal), anti-NPY (sc-14727, goat polyclonal), anti-GPR120 (sc-99105, rabbit polyclonal), anti-STAT3 (rabbit polyclonal, Abcam (Cambridge, MA). All the chemicals used in the real-time PCR experiments were obtained from Invitrogen and Applied Biosystems.

**Intraperitoneal insulin tolerance test (ipITT)**

After 6 h of fasting, CT, HF, FS- and OL-substituted mice groups were submitted to an insulin tolerance test (1 U/kg body weight of insulin). Mice were injected with insulin and blood samples were collected at 0, 4, 8, 12 and 16 min from the tail vein for serum glucose determination. The constant for the rate of serum glucose disappearance was calculated using the formula 0.693/biological half-life (t1/2). The plasma glucose t1/2 was calculated from the slope of last square analysis of the plasma glucose concentration during the linear phase of decline [15].

**Intraperitoneal glucose tolerance test (ipGTT)**

After 6 h of fasting, mice were submitted to a glucose tolerance test (1 U/kg body weight of insulin). Mice were injected with insulin and blood samples were collected at 0, 4, 8, 12 and 16 min from the tail vein for serum glucose determination. The constant for the rate of serum glucose disappearance was calculated using the formula 0.693/biological half-life (t1/2). The plasma glucose t1/2 was calculated from the slope of last square analysis of the plasma glucose concentration during the linear phase of decline [15].

**Feeding behaviour**

Rats deprived of food for 6 h with free access to water were icv injected (2μl) with solutions containing albumin (75 μM) or leptin (1.0 μM). Thereafter, diets were reintroduced and food intake was determined at the end of a 12-h period.

**Icv cannulation**

For icv cannulation, Wistar rats were used after 8 weeks of treatment with CT or HF diets. The rats were stereotaxically instrumented under sodium thiopental [15 mg (kg body weight)−1] anesthesia using a Stoelting stereotaxic apparatus, according to a previously described method [5]. Cannula efficiency was tested 3 d after cannulation by the evaluation of the drinking response elicited by icv angiotensin II [16]. Stereotaxic coordinates were anterior-posterior, 0.2 mm/lateral, 1.5 mm/depth, 4.0 mm. Icv-cannulated rats were treated with 2 μl of each fatty acid for 7 d. Controls were treated with a similar volume of albumin. Fatty acids for icv injection were always diluted in ultrapure water containing HBP detergent (0.1%) and fatty acid free BSA (75 μM). The volumes injected were always 2 μl/dose. The final concentration of fatty acids was always 225 μM. In some experiments, rats were treated icv with pure oleic, linolenic or stearic acids (225 μM). LPS contamination of the fatty acids, HBP and BSA preparations were evaluated by Limulus amoebocyte lysate assay produced by Associates of Cape Cod. LPS in the diets were evaluated by HPLC as described below. Only trace amounts of LPS (ranging from 0.030 to 0.070 EU/nmol) were detected in the reagents. According to a previously study [17], these levels of LPS do not interfere with the results.

**HPLC**

Determination of general lipid content and LPS in diets was performed using a HPLC method described previously [18]. Briefly, fatty acids were derivatized with 4-bromomethyl-7-coumarin and the analysis performed in a Shimadzu model LC-10A liquid chromatograph. The samples were eluted using a C8 column (25 cm × 4.6 id, 5 μm of particles) with a C8 precolumn (2.5 cm × 4.6 id, 5 μm of particles), 1.0 ml/min of acetonitrile/water (77%/23%, v/v) flow and fluorescence detector (325 nm

---

**Figure 1. Experimental protocols.** A, Four-week old male Swiss mice were fed regular chow (CT) or high-fat diet (HF) for eight weeks and then randomly divided into eight groups: CT mice, maintained for another eight weeks on the same CT diet; or HF mice which were either maintained on the same HF diet; or transferred to diets containing substitution of lard by olive or flax seed oils to final concentrations of 10, 20 or 30%, according to Table 1. At the end of the experimental period, the mice were submitted to a glucose tolerance test (GTT) and an insulin tolerance test (ITT), four days later, feeding behavior was evaluated and samples were obtained for immunoblotting (IB) and real-time PCR (RT-PCR). B, Four-week old male Wistar rats were fed for eight weeks on CT or HF diets and then submitted to intracerebroventricular (icv) cannulation. Drinking response elicited by angiotensin II (All) was tested three days after cannulation and responsive rats were treated icv with either o3, o9, stearic acid (SA) or diluents (Alb) for seven days. Feeding behavior and body mass were determined throughout the experimental period. At the end of the period some rats were randomly selected for histology, IB and RT-PCR; the remainder of the rats was followed up for feeding behavior for an additional five days after the discontinuation of icv treatment.

doi:10.1371/journal.pone.0030571.g001
excitation and 395 nm emission). For quantification of fatty acids, the capacity factor, elution sequence, linearity, recovery, precision, interference, and limit of detection were determined. The lower limit of detection was 1.0 pg and highly purified LPS was used as a tracer.

**Gas chromatography**

The relative amounts of fatty acids in the diets, blood and hypothalamus were determined by gas chromatography, using a Shimadzu Model 17A, under the following operating conditions: fused silica capillary column (100 x 0.25 mm; SP-2560); hydrogen as the carrier gas, with a flow rate of 20 cm/s; oven temperature, initially 140°C for 5 min, was increased up to 240°C at 4°C/min and maintained at 240°C for 30 min; injector, split ratio was 1:50, temperature 250°C; vaporization and detector temperatures were 250°C and 260°C, respectively. The injection volume was 1 μl of sample solution. The retention times of methyl ester standards (Sigma Aldrich) were used to identify peaks. Lipids extracted from diets, blood and hypothalamus were stored at −20°C protected from light.

**Immunohistochemistry and histology**

Epidermal fat specimens were dehydrated with ethanol, cleared with xylene, and embedded in paraffin wax (Merck, São Paulo, Brazil). After inclusion, 4 mm sections were obtained on a microtome (CUT model 443, Olympus). Epidermal fat sections were stained with hematoxylin and eosin (Merck). Photomicrographs were obtained as described below. The mean area of adipocytes (average surface area of 30 randomly sorted adipocytes, per animal) was determined by the Imagelab Analysis software (ImageLab, Modena, Italy, v. 2.4). Hydrated, 4 μm sections of paraffin-embedded, central nervous system specimens were obtained from rats treated for 8 weeks with CT or HF diets plus the respective icv treatment (system specimens were obtained from rats treated for 8 weeks paraformaldehyde-fixed, paraffin embedded, central nervous topographical views of the regions to be studied were obtained by according to the landmarks given in a stereotaxic atlas [20]. The hypothalami were sectioned from and documentation of results were performed using a Leica FW 4500 B microscope. The hypothalami were sectioned from at room temperature with 2% rabbit pre-immune serum and then incubated for 12 h, at 4°C, in a moister chamber, with an anti-F4/80 (1:50) or an anti-GRP120 (1:100). Sections incubated with the anti-F4/80 antibody were then incubated with a FITC conjugated anti-rabbit IgG secondary antibody. Sections incubated with the anti-GRP120 antibody were then incubated with the second primary antibody against NPY (1:50) for another 12 h, at 4°C, in the moister chamber. Finally, sections were incubated with FITC-, and rhodamine-conjugated secondary antibodies. Analysis and documentation of results were performed using a Leica FW 4500 B microscope. The hypothalami were sectioned from Bregma -2.1 to -2.3 mm. The anatomical correlations were made according to the landmarks given in a stereotaxic atlas [20]. The topographical views of the regions to be studied were obtained by hematoxylin-eosin staining of consecutive sections.

**Protein analysis by immunoprecipitation and immunoblotting**

As soon as anaesthesia was assured by the loss of pedal and corneal reflexes, the skull was opened and the basal diencephalon, including the preoptic area and hypothalamus, was excised. The hypothalami were pooled and 125 μg of protein was used as a whole tissue extract. In some experiments, fragments of the brown adipose tissue (BAT) were used for whole protein extract preparation. For evaluating leptin or insulin responsive proteins, samples were obtained 15 min after leptin/insulin (2 μl, 1 μM solution of either leptin or insulin) injection, as shown for Kim and colleagues [21]. We carried out similar proceedings to extract the nice mice to collect the hypothalami. Tissues were pooled, minced coarsely and homogenized immediately in extraction buffer (1% Triton X-100, 100 mM Tris, pH 7.4, containing 100 mM sodium pyrophosphate, 100 mM sodium fluoride, 10 mM EDTA, 10 mM sodium vanadate, 2 mM phenylmethanesulphonylfluoride (PMSF) and 0.1 mg ml⁻¹ aprotinin) at 4°C with a Polytron PTA 208 generator (Brinkmann Instruments model PT 10/35) operated at maximum speed for 15 s. The extracts were centrifuged at 9,000 g and 4°C in a Beckman 70.1 Ti rotor (Palo Alto, CA, USA) for 45 min to remove insoluble material, and the supernatants of these tissues were used for protein quantification, using the Bradford method [22]. Proteins were denatured by boiling in Laemmli sample buffer. Samples containing 125 μg of protein extracts were separated by SDS-PAGE, transferred to nitrocellulose membranes and blotted with antibodies against TNF-α, IL-6, IL-10, iNOS, JNK, p-JNK, p-IB-κB, SOCS3, caspase3, BAX, Bcl2, p-ACC, ACC, FAS, GPT-1, SCD, UCP-1, JAK, p-JAK2, STAT3, p-STAT3, AKT, p-Akt, FoxO1, and β-actin. Specific bands were labeled by chemiluminescence and visualization was performed by exposure of the membranes to RX-films. For the evaluation of GPR120 signal transduction, rats were acutely treated with either o3 or o9 fatty acids (225 μM) and hypothalamic protein extracts were prepared. For each analysis, 500 μg protein was used for immunoprecipi-

tation with GPR120, β-arrestin 2 or TAK1 antibodies. Immuno-precipitates were separated by SDS–PAGE and membranes were blotted with either β-arrestin or TAB1 antibodies.

**Real-time PCR.** Reverse-transcription was performed using total RNA from hypothalamic samples, as described previously [19]. NPY, POMC, CART and MCH mRNAs were measured in the hypothalamus of rats treated with CD or HF diets and in intracerebroventricular cannulated rats treated with linoleic and oleic acid. Intron-skipping primers for NPY, AGRP, MCH and POMC were obtained from Applied Biosystems. Glyceraldehyde-3-phosphate dehydrogenase primers (Applied Biosystems) were used as a control. Real-time PCR analysis of gene expression was performed in an ABI Prism 7700 sequence detection system (Applied Biosystems). The optimal concentration of cDNA and primers, as well as the maximum efficiency of amplification, were obtained through five-point, two-fold dilution curve analysis for each gene. Each PCR contained 3.0 ng of reverse-transcribed RNA, 200 nM of each specific primer, SYBR SAFE PCR master mix, and RNase free water added to a 20 μl final volume. Real-time data were analyzed using the Sequence Detector System 1.7 (Applied Biosystems).

**Statistical analysis**

Specific protein bands present in the blots were quantified by digital densitometry (ScionCorp). Analysis of variance was used to compare independent samples. Mean values ± SEM obtained from densitometry scans and from real-time PCR measurements, were subjected to analysis of variance (ANOVA) or Student's t-test for unpaired data, and differences were considered significant at *P*<0.05.
in the blood, but produced a significant reduction of total blood content of saturated fatty acids, as compared to mice fed on HF (Table 3). In the hypothalamus, the HF diet produced significant increases of C20:0 and C22:0, as compared to mice fed on chow (Table 4). The 10% FS substitution resulted in reductions of the C20:0 and C22:0 levels and reduction of the α6:α3 ratio from 1:1.29 to 1:1.65 in the hypothalamus, as compared to mice fed on HF (Table 4). The 10% OL substitution resulted in significant reductions of the relative C20:0 and C22:0 contents in the hypothalamus, as compared to mice fed on HF (Table 4).

FS and OL substitutions in the diet reduce food intake and body mass gain

In order to evaluate the impact of the dietary fatty acid composition on a number of metabolic parameters, mice were initially fed on a saturated-rich HF diet for 8 weeks and then...
randomly assigned to diets containing stepwise substitution fractions of FS and OL, according to Table 1. The substitution of diet lard by FS or OL significantly reduced food intake, independently of oil type and diet composition (Fig. 2A). The impact of diet fatty acid substitution on body mass variation was dependent on composition but not on unsaturated fatty acid type. Thus, increasing the fraction of unsaturated fatty acid in the diet significantly reduced the body mass gain during the 60-day experimental period (Fig. 2B). Interestingly, when evaluating body mass variation during the four 15-day periods that spanned the whole experimental time, it was evident that diets containing lower fractions of unsaturated fatty acids (10 and 20%) led to an initial body mass increase, which was followed by reduction in body mass gain, or even loss of body mass. This was not observed in diets containing 30% FS or OL, which led to low body mass gain or even body mass loss, in all the four 15-day periods (Fig. 2C–2E). The effects herein described were not due to palatability, because except for a discrete preference for HF against chow, no differences in preference were found when comparing each of the unsaturated fatty acid substitutions against HF (Fig. 2F).

FS and OL substitutions in the diet improve insulin action and glucose homeostasis

In humans and experimental animals, the consumption of high-fat diets leads to insulin resistance and glucose intolerance [23,24]. To determine the impact of unsaturated fatty acid substitution on insulin action and glucose homeostasis, mice fed on the distinct unsaturated fatty acid-substituted diets were submitted to insulin and glucose tolerance tests. As depicted in Figures 3A and 3B, unsaturated fatty acid substitution, irrespectively of substitution fraction or fatty acid type, produced significant reductions in Kitt and the glucose area under curve, during a GTT, respectively.

FS and OL substitutions reduce diet-induced hypothalamic inflammation and correct the response to nutrient sensing signals

A number of previous studies have shown the effect of saturated-rich high-fat diets on the induction of hypothalamic inflammation [4,5,8]. The induction of inflammatory gene expression in the hypothalamus can be detected as early as 2w after the introduction of the HF diet (Figure S1). The substitution of saturated by unsaturated fatty acids in the diet promoted dose- and fatty acid type-independent reductions in the expressions of the inflammatory markers pIκB-α (Fig. 4A), pJNK (Fig. 4B), TNF-α (Fig. 4C), SOCS3 (Fig. 4D) and iNOS (Fig. 4E), while increasing the expression of the anti-inflammatory cytokine, IL-10 (Fig. 4F), in the hypothalami of mice. In addition, ω3- and ω9-rich diets led to up to 3-fold increases in the hypothalamic expression of the anti-apoptotic protein Bcl-2 (Fig 4I), while reducing the apoptotic proteins, caspase-3 (Fig. 4G) and Bax (Fig. 4H). All these effects were accompanied by the
inhibition of ACC activity (Fig. 4J), while decreasing the expression of FAS (Fig. 4K) and increasing CPT-1 (Fig. 4L). 

Icv $\omega$3 and $\omega$9 treatments reduce food intake and body adiposity

To determine the direct effect of unsaturated fatty acids on hypothalamic function, rats were submitted to icv cannulation and treated with $\omega$3, $\omega$9 or stearic acid for seven days. Daily icv injections of $\omega$3 or $\omega$9 fatty acids significantly reduced spontaneous food intake (Fig. 5A) and enhanced the anorexigenic effect of leptin in both control and HF rats (Fig. 5B). This resulted in significant body mass loss (Fig. 5C) and reduction of epididymal fat content (Fig. 5D), with reduction of mean adipocyte diameter (Fig. 5E and 5F). Discontinuation of the icv injections with either

**Figure 4. Signal transduction in the hypothalamus.** Hypothalamic total protein extracts obtained from Swiss mice fed on regular chow (CT), high-fat diet (HF), flax seed- (FS) or olive oil- (OL) substituted (10, 20 or 30%) diets for eight weeks were used in immunoblotting (IB) experiments to evaluate protein expression and/or activity. Specific antibodies against phospho-IkB-α (P-IkBα) (A), phospho-JNK (P-JNK) (B), TNF-α (C), SOCS-3 (D), iNOS (E), IL-10 (F), Caspase-3 (CASP-3) (G), BAX (H), Bcl-2 (I), phospho-ACC (P-ACC) (J), FAS (K) and CPT-1 (L) were used to identify respective protein targets. Loading was evaluated by re-probing the membranes with anti-β-actin (A, C-I, K and L), anti-JNK (B) or anti-ACC (J) antibodies. In all experiments, n = 5; #p<0.05 vs. CT and *p<0.05 vs. HF.

doi:10.1371/journal.pone.0030571.g004
unsaturated fatty acid resulted in a complete restoration of baseline feeding behavior (Fig. 5A).

Icv ω3 and ω9 treatments reduce hypothalamic inflammation and the expression of apoptotic proteins

Seven days of ω3 or ω9 icv treatment significantly reduced the hypothalamic expression of markers of inflammation, iNOS (Fig. 6A), IL-6 (Fig. 6B), TNF-α (Fig. 6C) and pJNK (Fig. 6E). The ω9 fatty acid was significantly more effective in reducing iNOS (Fig. 6A) and IL-6 (Fig. 6B), while ω3 fatty acid was significantly more effective in reducing pJNK (Fig. 6E). TNF-α was similarly affected by both unsaturated fatty acids (Fig. 6C). The reduction in hypothalamic inflammation, induced by ω3 and ω9 fatty acids, was also detected as a reduction in F4/80-positive cells in the arcuate nucleus (Fig. 6F). In addition, the hypothalamic expression of the anti-inflammatory cytokine, IL-10 was significantly increased by either ω3 or ω9 fatty acids (Fig. 6D). Moreover, both icv ω3 and ω9 produced a significant reduction in the hypothalamic expression of the pro-apoptotic protein, Bax (Fig. 6G), while ω3, but not ω9 fatty acid produced an increase in the expression of the anti-apoptotic protein, Bcl-2 (Fig. 6H).

Icv ω3 and ω9 treatment improve anorexigenic and pro-thermogenic signaling in the hypothalamus

Leptin and insulin provide the most robust anorexigenic and pro-thermogenic signals to the hypothalamus [25,26]. The icv treatment of rats with either ω3 or ω9 fatty acids significantly improved leptin signal transduction through JAK2 (Fig. 7A), STAT3 (Fig. 7B) and Akt (Fig. 7C) in lean rats. In addition, in HF rats, leptin signaling through JAK2 (Fig. 7D), STAT3 (Fig. 7E), Akt (Fig. 7F) and FOXO1 (Fig. 7G), as well as insulin signal transduction through Akt (Fig. 7H), were significantly improved. Proteins belonging to the hypothalamic nutrient sensing pathway were also modulated. Thus, ω3 and ω9 fatty acids produced an increase in ACC phosphorylation (Fig. 7I) accompanied by a reduction in FAS expression (Fig. 7J) and increased CPT1 (Fig. 7K) and SCD1 (Fig. 7L) expressions. All these effects were accompanied by reductions in the mRNA expressions of NPY (Fig. 8A) and MCH (Fig. 8B) and by the increase of POMC (Fig. 8C) and CART (Fig. 8D). The pro-thermogenic effect of the treatment with ω3 and ω9 was further evidenced by the increased expression of UCP1 in BAT (Fig. 8E).
Unsaturated fatty acids activate signal transduction through GPR120 in the hypothalamus

A recent study has identified GPR120 as the receptor mediating the anti-inflammatory and insulin-sensitizing actions of ω3 fatty-acids in monocytes [27]. To investigate if ω3 and ω9 fatty acids could act through the same receptor in the hypothalamus we first performed double-labeling immunofluorescence studies, which revealed the co-expression of GPR120 and NPY in cells of the arcuate nucleus (Fig. 9A and 9B). Next, we acutely injected ω3 or ω9 fatty acids icv and evaluated signal transduction through GPR120. Upon either ω3 or ω9 stimulation, GPR120 undergoes a rapid association with the scaffolding protein β-arrestin 2 (Fig. 9C), which is immediately followed by the association of β-arrestin 2 with TAB1 (Fig. 9D). Simultaneously, TAB1 dissociates from TAK1 (Fig. 9E), forwarding the GPR120 signal downstream.

Figure 6. Expression of inflammatory and apoptotic proteins in the hypothalamus of icv-treated rats. Wistar rats fed on a regular chow (CT) or on a high-fat diet (HF) and icv cannulated were treated for seven days with diluent (albumin, Alb), ω3 or ω9 fatty acids and then used in immunoblotting (IB) and immunofluorescence experiments. Specific antibodies against iNOS (A), IL-6 (B), TNF-α (C), IL-10 (D), phospho-JNK (P-JNK) (E), BAX (G), and Bcl-2 (H) were used to identify respective protein targets in hypothalamic samples. Loading was evaluated by re-probing the membranes with anti-β-actin (A-D, G and H) or anti-JNK (E). In F, 5 µm sections of the hypothalamus were labeled with an anti-F4/80 antibody. In all experiments, n = 5. In A-E, *p<0.05 vs. Alb; in A and B, #p<0.05 vs. ω3; in G and H, #p<0.05 vs. CT, *p<0.05 vs. Alb.
doi:10.1371/journal.pone.0030571.g006

Unsaturated fatty acids activate signal transduction through GPR120 in the hypothalamus

A recent study has identified GPR120 as the receptor mediating the anti-inflammatory and insulin-sensitizing actions of ω3 fatty-acids in monocytes [27]. To investigate if ω3 and ω9 fatty acids could act through the same receptor in the hypothalamus we first performed double-labeling immunofluorescence studies, which revealed the co-expression of GPR120 and NPY in cells of the arcuate nucleus (Fig. 9A and 9B). Next, we acutely injected ω3 or ω9 fatty acids icv and evaluated signal transduction through GPR120. Upon either ω3 or ω9 stimulation, GPR120 undergoes a rapid association with the scaffolding protein β-arrestin 2 (Fig. 9C), which is immediately followed by the association of β-arrestin 2 with TAB1 (Fig. 9D). Simultaneously, TAB1 dissociates from TAK1 (Fig. 9E), forwarding the GPR120 signal downstream.
Discussion

The present study was undertaken to evaluate the effect of the nutritional substitution of saturated by unsaturated fatty acids, and also the direct effect of unsaturated fatty acids on the modulation of hypothalamic inflammation and function in obesity. In modern societies, the progressive increase in the dietary consumption of saturated fatty acids is taken as one of the main determinants of obesity, and dietetic approaches aimed at substituting saturated by unsaturated fats have succeeded in reducing body mass and improving a number of metabolic parameters in overweight patients [23].

Saturated fatty acids, acting directly in the hypothalamus or as a component of the diet, induce inflammation by activating TLR4 signaling and ER stress, which leads to increased inflammatory gene transcription, hypothalamic dysfunction and eventually neuronal apoptosis [5,6]. These local effects are accompanied by progressive loss of the balance between food intake and energy expenditure, which result in increased adiposity and metabolic breakdown [2,28].

Figure 7. Effect of icv ω3 and ω9 on hypothalamic signaling. Wistar rats fed on a regular chow (CT) or on a high-fat diet (HF) and icv cannulated were treated for seven days with diluent (albumin, Alb), ω3 or ω9 fatty acids. In addition, in some experiments, rats were acutely treated with a single dose of either leptin (2 μl, 10^-6M: A-G) or insulin (2 μl, 10^-6M: H) and then used in immunoblotting (IB) experiments. Specific antibodies against phospho-JAK2 (P-JAK2) (A and D), phospho-STAT3 (P-STAT3) (B and E), phospho-Akt (P-Akt) (C, F and H), phospho-FoxO1 (P-FoxO1) (G), phospho-ACC (P-ACC) (I), FAS (J), CPT-1 (K) and SCD-1 (L) were used to identify respective protein targets in hypothalamic tissue. Loading was evaluated by re-probing the membranes with anti-β-actin (J-L), anti-JAK2 (A and D), anti-STAT3 (B and E), anti-Akt (C, F and H), anti-FoxO1 (G) or anti-ACC (I). In A-H, #p<0.05 vs. Alb (-), *p<0.05 vs. Alb (+); in I-L, #p<0.05 vs. CT, *p<0.05 vs. Alb.

doi:10.1371/journal.pone.0030571.g007
Due to the known anti-inflammatory actions of unsaturated fatty acids in other tissues or cell-types [12,13,14], we hypothesized that, by acting as nutrients and/or directly in the hypothalamus, these molecules could, at least partially, reduce inflammation and correct hypothalamic activity in the regulation of energy homeostasis. In the first part of the study, diet-induced obese mice were fed diets composed of a stepwise substitution of the saturated by unsaturated fatty acids. The substitutions of the fatty acid components in the diet resulted in increased relative amounts of unsaturated fatty acids, predominating oleic acid in the olive oil substituted diets and linoleic acid in the flax seed oil substituted diets. The FS substitution resulted in increased relative amount of ω3 in the blood and hypothalamus. However, OL substitution did not impact on the relative ω9 amount in either tissue. Instead, a reduction of saturated fat was achieved. We have no current explanation for that, but we suspect that the overall metabolism of ω9 avoids its excessive increase in the hypothalamic tissue. This is supported by the fact that the diets modulate enzymes involved in fatty acid metabolism such as FAS and SCD1, as shown by our experiments. As a consequence of fatty acid substitution there was a reduction in food intake to levels similar to control, an effect that was independent of fatty acid type and quantity. However, this was accompanied by a dose-dependent-like effect on body mass, with maximum effect in the 30% substituted diets, irrespectively of fatty acid type. Interestingly, most of the effect of the substituted diets occurred during the second half of the experimental period. In fact, in some conditions, mice presented an increase in body mass gain during the first 30 days. Nevertheless, even the groups presenting body mass gain at the beginning, reached the end of the experimental period with a significantly lower body mass gain, as compared to controls.

We next evaluated the effect of fatty acid substitution on whole body insulin action and glucose homeostasis. Similarly to the effect of the substituted diets on food intake, here, a complete restoration of insulin action and glucose homeostasis to levels similar to those of lean controls was obtained, independently of diet composition and fatty acid type. Since the effect of substitutions on body mass were dependent on the quantity of the unsaturated fatty acids, we believe the effect on insulin action and glucose homeostasis was simply due to the presence of the increased amounts of unsaturated fatty acids in the diets and not secondary to body mass reduction. In this regard, studies by L. Rossetti’s group have shown the direct effect of central administration of oleic acid on the control of peripheral glucose homeostasis, which depends, at least in part, on the neural control of hepatic gluconeogenesis [29,30,31].

Recent data have increased interest in the effects of hypothalamic inflammation on whole body energy homeostasis [20]. The activation of inflammatory signaling in this particular anatomical region is capable of modulating glucose homeostasis and thermogenesis, mostly by controlling neural inputs to specific organs [31,32]. This mechanism, acts in concert with inflammation-induced hypothalamic resistance to the anorexogenic hormones, leptin and insulin, to produce the multiple components of the complex phenotype observed in obesity. The reduction of hypothalamic inflammation in obesity corrects simultaneously feeding, thermogenesis and metabolic disarrangements, placing this phenomenon in a central position in the pathogenesis of obesity [4,5,8]. Here, when mice were fed unsaturated fatty acid-rich diets, a reduction in the hypothalamic expression of a number of inflammatory markers was achieved, which is in accordance with the results obtained in animal models treated with anti-inflammatory drugs [4,5,11], or harboring genetic modifications that impair inflammatory signaling [5,8]. In addition, the expression of pro-apoptotic proteins was decreased, while the signaling through the AMPK/ACC pathway was corrected, showing that the effect of the unsaturated fatty acid was broad, restoring, at least in part, all defects reported so far in animal models of obesity [4,5,6,33].

To determine whether the anti-inflammatory and metabolic effects observed with the diets were indeed due to the presence of increased amounts of unsaturated fatty acids, we next evaluated the direct effect of ω3 and ω9 in the hypothalamus. Both fatty acids induced a large reduction in spontaneous food intake, which was completely restored after discontinuation. A similar effect has been previously reported for oleic acid [31], and now we have extended this observation to linoleic acid. As a consequence of the reduction in feeding, both fatty acids promoted reductions in adiposity, with a reduction in mean adipocyte size. Of great importance, the fatty acids exerted a potent anti-inflammatory effect, reducing the hypothalamic expression of cytokines and inflammatory signaling proteins. In addition, the presence of activated microglial cells was restrained by either ω3 or ω9 icv treatments.

The effect of icv unsaturated fatty acids was not restricted to the inflammatory pathways, and significant improvement of leptin and insulin signal transduction in the hypothalamus was also achieved. This is of major interest in obesity because the impairment of
signal transduction through these pathways in the hypothalamus seems to constitute the molecular basis for obesity [2,34,35,36]. In addition, as for the diets, icv unsaturated fatty acids corrected signal transduction through the AMPK/ACC pathway. This pathway is involved in nutrient sensing and cross-talks with hormone signaling systems to control neurotransmitter expression [33,37].

Next, we determined the impact of the unsaturated fatty acids on the hypothalamic expression of neurotransmitters involved in the control of energy homeostasis. In general, animal models of obesity present increased expressions of the orexigenic, anti-thermogenic NPY and MCH and reduced expressions of the anorexigenic, pro-thermogenic POMC and CART [38,39]. Either ω3 or ω9 fatty acids reduced hypothalamic expression of NPY and MCH while increasing the expressions of POMC and CART. These results are somewhat similar to those achieved by other anti-inflammatory approaches [5,8]. Interestingly, both fatty acids significantly increased the expression of UCP1 in the BAT, suggesting that an increase in thermogenesis may play a role in the phenotypic changes obtained. In other animal models of obesity,
anti-inflammatory approaches also produced beneficial changes in the expression of UCP1 in BAT [40].

Finally, we showed that the unsaturated fatty acid receptor, GPR120 is expressed in the hypothalamus and is activated in response to αδ and e9 fatty acids. GPR120 was recently identified as an important mediator of the anti-inflammatory and insulin-sensitizing effects of unsaturated fatty acids in monocytes [27]. Upon ligand binding, GPR120 activates signal transduction through β-arrestin 2/Tab1, which switches-off the TLR4 and TNF inflammatory pathways, these effects were reproduced in the hypothalamus of obese rats. In addition, we show that GPR120 is expressed in NPY expressing neurons. We decided to test this particular co-expression because of the remarkable effect of the unsaturated fatty acids to reduce NPY expression, however, cells other than the NPY neurons were also stained by the GPR120 antibody (not shown). Since NPY is inhibited in response to leptin, and, in diet-induced obesity there is resistance to leptin action in the hypothalamus, it possible that upon unsaturated fatty acid stimulation, GPR120 present in NPY neurons can play a role reestablishing the action of leptin towards NPY gene expression inhibition.

In conclusion, unsaturated fatty acids can reproduce a number of the anti-inflammatory effects of TLR4 or TNF-α inhibition and, therefore, constitute an attractive nutritional approach to treat obesity. At least part of this effect may be mediated by the GPR120 receptor.

Supporting Information

Figure S1 Time course of high-fat diet (HF)-induced expression of inflammatory markers in the hypothalamus. Swiss mice fed on chow (CT) or HF for 2, 4 or 8 weeks were employed for determination of the hypothalamic expression of interleukin-1β (A-C) or tumor necrosis factor-a (D-E) transcripts by real-time PCR. In all experiments, n = 5; *p<0.05 as CT. (TIF)
