It was established that ultrasonic treatments (USTs) have practically no effect on the patterns of current flow in the Al-Al₂O₃-p-CdTe-Mo structure in the forward direction, namely, as in the absence of ultrasonic action, they appear in the sequence J~V, J~V², J~V⁵.3, and J~V². The effect of ultrasonic treatments affects only the magnitude of the flowing current; at low voltages, the current becomes somewhat larger, and at high voltages, it practically does not change. Changes in the magnitude of the flowing current are explained on the basis of the assumption that the recombination of nonequilibrium carriers in such a structure occurs through complex pair recombination complexes and, as a result of ultrasonic treatments, the number of both small acceptors and deep recombination centers increases.

1. Introduction

Currently, it is considered as an established fact that ultrasonic treatment (UST) affects structural defects and the electrophysical characteristics of semiconductors and semiconductor structures [1–8]. The advantages of UST compared with annealing and radiation exposure include the following features:

1. The absorption of ultrasonic waves in a solid occurs predominantly in areas of disturbances of the periodicity of its crystal lattice and, therefore, the ultrasonic effect is more local
2. The use of ultrasonic waves of different polarization and types allows to increase the selectivity of influence
3. By selecting the frequency of ultrasonic vibrations, it is possible to achieve resonant transformations in the defective subsystem

It is known that the electrophysical and photoelectric properties of heterojunctions and MOS structures strongly depend on the properties of the surface of semiconductors. Since various surface effects directly affect the reliability and stability of virtually all types of semiconductor devices, the study of surface physics using metal-dielectric-semiconductor (MOS) structures plays a large role in all semiconductor technologies. The authors of Ref. [9, 10] investigated surface states at the interface of the Al-Al₂O₃-p-CdTe structure. In the Reference [11], it was shown that such a structure has the property of an injection photodetector and amplifies the primary photocurrent even in the absence of an external bias voltage. In the work [12], we investigated the effect of ultrasonic treatments on the electrophysical properties of the Al-Al₂O₃-p-CdTe structure. Ultrasonic treatments were carried out at the frequency of 2.5 MHz with the power of $P = 1 \text{ W/cm}^2$ for 15 minutes. It was proved that UST significantly affects the fluctuations of surface charges at the interface and eliminates unstable point defects located in
the near-surface layer of a semiconductor. Experimental results have shown that the Al₂O₃ oxide layer formed between aluminum (Al) and cadmium telluride (CdTe) is of sufficient quality. It is proved that ultrasonic annealing of surface states in the upper half of the semiconductor bandgap at the interface of the Al-Al₂O₃-p-CdTe-Mo structure leads to a decrease in the surface recombination current, and this, in turn, provides an increase in the number of electrons injected from the aluminum side into the base; therefore, the forward current increases after the UST. A decrease in the reverse current is due to the annealing of surface states in the lower half of the semiconductor bandgap, since this decreases the probability of tunneling of nonequilibrium electrons accumulated at the interface from the base into the metal. Experimental results have shown that the Al₂O₃ oxide layer formed between aluminum (Al) and cadmium telluride (CdTe) is of sufficient quality. Since the Al₂O₃ oxide layer is the main element in the studied Al-Al₂O₃-p-CdTe-Mo structure, a change in its properties, including the concentration of defects and impurities in the dielectric oxide layers (surface states) should affect the electrophysical and photoelectric properties of the entire structure. Therefore, this work is devoted to the study of the effect of ultrasonic treatments (UST) on the processes of current transport in the Al-Al₂O₃-p-CdTe-Mo-structure.

2. Experimental

Film structures p-CdTe from a columnar structure of grains on a Mo substrate are obtained by the sublimation methods in a hydrogen flow. It should be noted that when using hydrogen as a carrier gas, the transport of the vaporized substance is carried out at relatively lower temperatures than in the case of other inert gas compositions. In the synthesis of CdTe films in a flow of hydrogen H₂, the determining factor affecting their growth rate is the degree of excess of the metal components of cadmium vapor over the stoichiometric composition. This is explained by the fact that the components of Cd atoms are more volatile relative to Te atoms in CdTe vapor and is confirmed by the results of studies of the microstructure of the surface of the Al-p-CdTe-Mo structure on the surface of the CdTe film, as well as on the surface of aluminum. The elemental composition of the structure was studied using a JEOL JXA-8900R electron microprobe analyzer, using energy dispersive spectrometer (EMF) LINK ISIS (Japan). It was revealed that the atomic ratio of the components in the CdTe film is Cd/Te = 0.986 ± 1, which corresponds to the weak p-type conductivity of CdTe. Microcrystals of CdTe films grown at a substrate temperature Tₜ = 670°C have high resistivity (ρ = 10⁶÷10¹¹ Ω•cm) and have a mixed hexagonal and cubic structure. They have a columnar structure of grains in the direction of growth and were practically a single crystal. The cross-sectional grain sizes range from 100 to 150 μm. The thickness of the p-CdTe films was initially 40–50 μm, so that the grains penetrate the entire thickness of the film. The resulting films were brought to the required thickness (8–10 μm) by grinding and polishing. Since at base thicknesses d ≤ 5 μm, the Al-p-CdTe-Mo diode structure abruptly loses its rectifying properties. For example, the rectification coefficient, defined as the ratio of forward and reverse current at a fixed voltage (5 V), with a base thickness d = 8–10 μm is four to five orders of magnitude, and at d ≤ 5 μm, it is only two orders of magnitude at the same value bias voltage. This is explained by the fact that the number of structural defects, including various complexes, inclusions, in the growing film at a distance of ~5 μm from the molybdenum substrate begins to increase sharply. The base thickness of the structure under study is d = 10 μm. In the course of sublimation in a stream of hydrogen, strongly compensated high-resistance large-block p-CdTe films of hole conductivity are synthesized. The p-CdTe films were synthesized from CdTe powders containing several impurities: copper, silver, and zinc. Therefore, strongly compensated high-resistance large-block p-CdTe films are probably formed.

The lifetime of minority charge carriers-electrons is τ~10⁻⁸÷10⁻⁷ s. The value of τ is determined from the relaxation of nonequilibrium current carriers at a low level of excitation, both in the absence of voltage and at various applied voltages [13]. Nonequilibrium carriers were excited by an electric signal that was supplied from the calibrated pulse generator G5-55 of the voltage (5 V), with a base thickness d = 8–10 μm and duty cycle not less than 5×10⁻⁸ s. The relaxation curve for the concentration of nonequilibrium variables at various stresses is described by an exponential dependence of the form as follows:

\[ \Delta n = n_1 e^{-t/\tau}, \]

where \( t \) is the time and \( \tau \) is the relaxation time constant. According to expression (1), value of the time constant was determined: \( \tau_1 = 2 \cdot 10^{-8} \) s in the absence of voltage and \( \tau_2 = 10^{-7} \) s at a constant voltage \( V = 1.2 \) V corresponding to the end section of a sharp increase in the current.

MOS structures were created on the surface of the films obtained by sputtering aluminum (Al) in vacuum (~10⁻⁵ Torr) [14]. In this case, the frontal aluminum contact had a thickness of ~40÷50 nm and an area of \( S \approx 1 \) cm². Here, the role of the rear electrical contact is played by the Mo substrate. The performed X-ray diffraction analysis showed [15, 16] that a thin Al₂O₃ oxide layer with a thickness of ~30 nm is formed in the technological process. This layer plays a very important role in the work of the obtained structure; it is thanks to it that it is not a simple metal-semiconductor structure that is obtained, but a MOS structure, i.e., Al-Al₂O₃-p-CdTe-Mo (Al metal, Al₂O₃, p-CdTe semiconductor, and Mo play the role of an ohmic contact). It is known that Al₂O₃ can be considered as a wide-gap n-type semiconductor. Thus, the obtained Al-Al₂O₃-p-CdTe-Mo structure can be represented as a \( R_{sub}-n^-p-R_{base} \) structure with a long p-base, the scheme of which is shown in Figure 1.
models of such compound complexes are collected. In this case, the scheme of recombination occurring through such a two-level complex will be approximately the same for all models. It is shown in Figure 4. It is assumed that the difference $E_1 - E_2$ is very small, so you can ignore it. It was also shown in Ref. [18] that the rate of recombination occurring through all such complexes can be represented as

$$U = N \frac{c_{n1} c_{p2} (p n - n_1^2)}{c_{n1} (n + n_{11}) + c_{p2} (p + p_{12}) + \tau n c_{n1} c_{p2} p n},$$

(2)

where $N$ is the concentration of complexes, $c_{n1}$ is the coefficient of electron capture from the conduction band to the upper level $E_1$, $c_{p2}$ is the coefficient of hole capture from the valence band to the lower level $E_2$. $\tau$ is the time of the intracomplex electron exchange, i.e., the electron exchange time between the levels $E_1$ and $E_2$, and $n_{11}$ and $p_{12}$ are analogues of the Shockley–Read statistical factors for levels $E_1$ and $E_2$, lying inside the bandgap and forming a pair recombination complex as follows:

$$n_{11} = N e^{-\left(E_r - E_i/kT\right)},$$

$$p_{12} = N e^{-\left(E_i - E_r/kT\right)}.$$  \hspace{1cm} (3)

In expression (2), the last term in the denominator describes the intracomplex electron exchange. When this member is small, i.e.,

$$c_{12} p n \ll c_{n1} (n + n_{11}) + (p + p_{12}),$$

(4)

then expression (2) is practically no different from the usual expression of the Shockley–Read statistics. In this case, the I-V characteristic for a sufficiently long diode ($d/L \gg 1$) is described by the well-known Lambert law as follows:

$$V \approx \frac{8 d^2 J}{3 \mu p n \tau r_n N_A} = B_0 \sqrt{J},$$

(5)

where $\mu_n$ is the electron mobility, $\tau_r$ is the electron lifetime, $\mu_p$ is the hole mobility, $J$ is the current density, and $d$ is the base thickness.

As already noted in Ref. [19], the Al-Al$_2$O$_3$-p-CdTe–Mo structure can be considered as an n'-p structure with two ohmic metal contacts and a long base $d/Ln \approx 10–20$, where $d$ is the length of the $p$ base, i.e., the CdTe layer, and $Ln$ is the diffusion length of minority carriers, i.e., electrons. By virtue of this, expression (5) well explains the first quadratic section.

As can be seen from Figure 1, the I-V characteristic at a low level of excitation, the dependence of current on voltage is described by a linear dependence and then a quadratic part appears.

Using the experimental results, we calculate the value of the product of mobility by the electron lifetime before the UST: $\mu_n \tau_n \approx 6.15 \times 10^{-6} \text{cm}^2/\text{V.s}$.

characteristic $I \sim V^n$, including the part of the sharp increase. Composing a straight line equation for two given experimental points $(J_1, V_1$ and $J_2, V_2$), we determine the voltage value as follows:

$$V = V_1 - \frac{V_1 - V_2}{J_2 - J_1} I_1$$

(8)

which is equated to the value $A = (b + 1)d^2N_R/N_{rs} \mu_s \tau_i$ from formula (6); then using this expression, we determine the parameter $N_R/\tau_i$. To determine the parameters, three experimental points $(V_1, J_1)$, $(V_2, J_2)$, and $(V_3, J_3)$ were chosen from the part of the sharp increase of current, and for them, two equations were compiled to determine the coefficients $B$ and $D$ as follows:

$$B = \frac{V_2 - V_1}{\sqrt{J_2} - \sqrt{J_1}} - D\left((1/\sqrt{J_1}) - (1/\sqrt{J_2})\right)$$

$$D = \frac{(V_3 - V_2) - (V_2 - V_1)}{(1/\sqrt{J_2}) - (1/\sqrt{J_3})} - \frac{(V_3 - V_2) - (V_2 - V_1)}{(1/\sqrt{J_1}) - (1/\sqrt{J_2})} - \frac{(V_3 - V_2) - (V_2 - V_1)}{(1/\sqrt{J_2}) - (1/\sqrt{J_3})}$$

(9)

Then, equated them to the analytical values from formula (6). Next, substituting $d = 10 \mu m$, $\mu_s = 100 \text{cm}^2\cdot V\cdot s$, and $N_A \approx 10^{10} \text{ cm}^{-3}$ in these expressions, we determine the parameters: $\mu_s C_i 1/\varepsilon_i \tau_i$. Then, using the formula (7), we determine the concentration of injected electrons $n(0)$ at the beginning and at the end of the third section. All parameters calculated from this part of the I-V characteristics are given in Table 1.

After the part of the sharp current increase, a quadratic part reappears. Such a sequence of I-V characteristics, according to the theory of [18], appears when the recombination rate through the complexes reaches full saturation $U \equiv N_R/\tau_i$, in which case the quadratic I-V characteristic is described by the expression [18] as follows:

$$V = \frac{(b + 1)d^2N_R}{2N_{rs} \mu_s \tau_i} + \frac{d \sqrt{J}}{q \mu_s (b + 1)}$$

(10)

The parameters determined from this site before and after USTs are, respectively, equal: $N_R/\tau_i \approx 2.45 \times 10^{17} \text{ cm}^{-3} \cdot \text{s}^{-1}$ and $N_R/\tau_i \approx 2.6 \times 10^{17} \text{ cm}^{-2} \cdot \text{s}^{-1}$, which are also listed in Table 1. The obtained $N_R/\tau_i$ values show that, at the same voltage value, the current in the second quadratic part should practically not change, which confirms well the I-V characteristic as shown in Figure 1.

4. Conclusion

Thus, the experimental effect of UST on the structure Al-Al$_2$O$_3$-p-CdTe-Mo shows that, in the forward direction of the applied voltage, the current, as a result of the action of USTs, first increases slightly and then practically does not change. These facts clearly indicate that the physical nature of recombination processes changes as the current increases. At first, recombination processes take place under conditions when intracomplex exchange is insignificant, and the pair compound-complex behaves like a simple Shockley–Read trap. And then, at higher levels of injection, the role of intracomplex electron exchange increases, then parts of faster increase, and the second quadratic part appears. We would like to emphasize that these two parts, despite the external similarity, have a different physical nature. This is clearly seen from a comparison of formulas (4) and (10). In formula (10), we see the value of the time of intracomplex exchange, which is not in expression (4). This explains the different influence of USTs on the first and second quadratic parts. Apparently, the UST removes not only surface effects, as was noted in Ref. [12], but also volumetric ones, as a result of which the concentration of dopants and recombination complexes increases, which leads to an increase of current in the first quadratic part and changes it only a little in the second one.

In conclusion, we would like to emphasize that the study of the influence of USTs on current transport processes in the Al-Al$_2$O$_3$-p-CdTe-Mo structure unambiguously confirms the validity of the assumption that recombination processes in this structure occur through the compound pair recombination complex.
