(Dated: August 23, 2020)

In triangular lattice structures, spatial anisotropy and frustration can lead to rich equilibrium phase diagrams with regions containing complex, highly entangled states of matter. In this work we study the driven two-rung triangular Hubbard model and evolve these states out of equilibrium, observing how the interplay between the driving and the initial state unexpectedly shuts down the particle-hole excitation pathway. This restriction, which symmetry arguments fail to predict, dictates the transient dynamics of the system, causing the available particle-hole degrees of freedom to manifest uniform long-range order. We discuss implications of our results for a recent experiment on photo-induced superconductivity in \( \kappa-(\text{BEDT-TTF})_2\text{Cu[N(CN)]}_2\text{Br} \) molecules.

**Introduction** – Identifying and understanding the processes which prevent thermalization and decoherence in driven-dissipative quantum systems [1] is a unifying theme in ultracold atoms and condensed matter research [2, 3]. This comes with the potential to realize and functionalize exotic out-of-equilibrium quantum phases, both for the continued progress of fundamental research and for wider technological purposes. In ultrafast materials science, the counterintuitive experimental observation of light-induced superconductivity [4–12] has stimulated the field. In these experiments intense laser pulses have been reported to induce superconducting-like features, such as an inverse-frequency divergence of the imaginary part of the optical conductivity and vanishing resistivity, well above the materials’ equilibrium critical temperatures, \( T_c \).

In a very recent experiment, specific vibrational modes of the charge-transfer salt \( \kappa-(\text{BEDT-TTF})_2\text{Cu[N(CN)]}_2\text{Br} \) were resonantly excited with mid-infrared radiation and the above-mentioned optical features were induced at temperatures several times higher than \( T_c \) [11]. Moreover, following excitation, a large gap in the real part of the optical conductivity opened up – a feature not seen when cooling the molecular crystal below \( T_c \). These results suggest a different mechanism for superconductivity compared to that when cooling the material. Within Ref. [11], a minimal microscopic two-rung triangular Hubbard lattice, with time-dependent parameters under resonant driving of specific phonon modes, was proposed as a model for the experiment.

A number of theoretical studies have explored the effects of carefully-tuned coherent driving on the prethermal dynamics of one and two dimensional bi-partite fermionic lattice models [13–20]. These studies are motivated by the opportunities arising from having dynamical time-dependent Hubbard parameters, which have been experimentally realised in contexts ranging from quantum simulators [21] to strongly-correlated materials via electronic [22–24] as well as vibrational excitations [25]. Their relevance, however, to organic materials such as the \( \kappa-(\text{BEDT-TTF})_2X \) compounds is unclear, due to the dimerized \( \text{BEDT-TTF} \) molecules forming a half-filled triangular, non bi-partite lattice [26–29]. Instances of the triangular Hubbard model, alongside other non-bipartite Hubbard lattices, do not possess the same symmetries as their hypercubic counterparts and the frustration and hoppings anisotropy can lead to rich equilibrium phase diagrams containing unique states of matter [30, 31].

In this paper we demonstrate how the interplay between such equilibrium states and generic periodic driving manifests complex nonequilibrium behavior in a triangular Hubbard model. Motivated by the results of Ref. 11, and the opportunity to explore the many-body dynamics of a driven frustrated system, we consider the time-dependent two-rung triangular Hubbard model and identify two distinct phases when driving the ground state out of equilibrium. Beneath a critical value of the hopping integral \( \tau' < \tau'_c \) there is a unique phase where the particle-hole excitation pathway is unexpectedly blocked. This impedance, which symmetry arguments fail to predict, causes the driving to establish amplified, coherent, long-range particle-hole order in the available degrees of freedom. As \( \tau' \) increases across the critical value, \( \tau'_c \), this restriction in the particle-hole channel is lifted and the driven system cannot dynamically sustain order due to the creation of a number of incommensurate particle-hole excitations.

We proceed to identify the origin of these distinct regimes - a rich ground state phase diagram with properties not seen in hypercubic realisations of the Hubbard model. When \( \tau' < \tau'_c \), the system forms a spin-wave condensate with an extensive interference pattern induced by the anisotropic geometry of the system. The con-
FIG. 1. First 8 sites of the two-rung triangular Hubbard model described by Eq. (1). The model has a time-dependent nearest-neighbor hopping $\tau(t)$, static vertical hopping $\tau'$, and a time-dependent local Hubbard interaction $U(t)$. The outer (blue) vs central (grey) sites represent a bi-partite splitting of the lattice in the limit $\tau' = 0$.

densed nature of this initial state prevents the driving from causing excitations in the particle-hole SU(2) pathway and leads to the observed induction of long-range order. For $\tau' > \tau'_c$ this spin-wave condensate is depleted and the driving produces excitations which instigate the decay of any particle-hole correlations.

Finally we show how, even for a small amplitude pulse, driving the spin-condensed initial state near resonance causes rapid relaxation towards a doublon-η solubility. On a bi-partite lattice, there are two SU(2) symmetries, known as the ‘spin’ and ‘η’ symmetries [37], which play a significant role in the physics of the model. For example, driving/dissipative terms which preserve the η symmetry have been shown to guide the system into steady states with long-range correlations in the η channel, a phenomenon named heating-induced order [38].

Here we focus on the role of heating in the dynamics of a driven non-bipartite two-rung triangular Hubbard model, where the η symmetry does not exist. The Hamiltonian is

$$H(t) = -\tau(t) \sum_{i,j \in (n.a.),\sigma} (c_{\sigma,i}^\dagger c_{\sigma,j} + h.c) - \tau' \sum_{i,j \in (vert.),\sigma} (c_{\sigma,i}^\dagger c_{\sigma,j} + h.c) + U(t) \sum_i n_{\uparrow,i} n_{\downarrow,i},$$  

where $n_{\sigma,i}$, $c_{\sigma,i}^\dagger$ and $c_{\sigma,i}$ are, respectively, number, creation and annihilation operators for fermions of spin $\sigma \in \{\uparrow, \downarrow\}$ on site $i$. In Eq. (1), the first summation is a time-dependent hopping term, with strength $\tau(t)$, over the diagonal nearest-neighbor bonds pictured in Fig. 1. The second summation is the hopping term $\tau' H_V$ over the vertical bonds and the last term is a time-dependent interaction term, with strength $U(t)$. We consider a half-filled lattice with $L$ sites and a total magnetisation of 0.

The time-dependence of the nearest-neighbour hopping and interaction strengths is

$$\tau(t) = \bar{\tau}(1 + A_\tau \sin^2(\Omega t) \exp\left(-\frac{(t - T_p)^2}{2T_w^2}\right)), \quad U(t) = \bar{U}(1 + A_U \sin^2(\Omega t) \exp\left(-\frac{(t - T_p)^2}{2T_w^2}\right)),$$

which constitutes a fairly general parametrisation of the Hamiltonian parameters. In Eq. (2), $A_U$ and $A_\tau$ are the amplitudes of the modulation of $U$ and $\tau$ relative to their equilibrium values $\bar{U}$ and $\bar{\tau}$. The frequency of the oscillations is $\Omega$, whilst $T_p$ and $T_w$ describe the offset and width of the Gaussian envelope containing these oscillations. Our observations in this paper are not specific to the parameters of the driving. In the Supplemental Material (SM) we demonstrate our results choosing different parameters to those in the main text [39].

We start by identifying the symmetry structure of $H(t)$. Firstly, we show that there is a permanent spin SU(2) symmetry $[H(t), S^{\pm}, S^z] \equiv 0$ where $S^{\pm}$ and $S^z$ are the total spin raising/lowering and counting operators respectively [35]. We also find

$$[H(t), \eta^\dagger] = 0, \quad [H(t), \eta^\dagger \eta] = [\tau' H_V, \eta^\dagger \eta] \propto \tau', \quad (3)$$

where

$$\eta^+ = \sum_{i=1}^L f(i)c_{\uparrow,i}^\dagger c_{\downarrow,i}^\dagger, \quad \eta^- = \sum_i (n_{\uparrow,i} + n_{\downarrow,i} - 1), \quad (4)$$

and $\eta^+ = (\eta^\dagger)^\dagger$ are the total η operators and act on the doublons (locally paired fermions) and holons (empty sites) within the lattice. In Equation (4), $f(i)$ takes the value +1(-1) for the blue (grey) lattice sites in Fig. 1. Equation (3) reveals that for finite $\tau'$ the system does not possess an η SU(2) symmetry due to the presence of the vertical hopping term $H_V$. We emphasize that even in the bi-partite limit, $\tau' \to 0$, the system is not equivalent to the 1D Hubbard model due to the differing co-ordination numbers on the blue vs grey sites.

With this knowledge of the symmetries in hand, we extend the methodology of [40–42] and propose that, in the long-time limit of $H(t)$, the system will reach a state of maximum entropy subject to the constraint that expectation values of conserved quantities must be preserved. If $H(t)$ possesses an SU(2) symmetry, this constraint leads to heating-induced order, with the long-time state guaranteed to have uniform, long-range correlations in the conserved symmetry sector [38, 43]. Meanwhile, for the
symmetries that $H(t)$ does not preserve, a large number of incommensurate excitations will be created - causing the decay of correlations in the corresponding sectors [38]. Hence we expect that for finite $\tau'$ large amplitude driving from Eq. (2) should cause the particle-hole correlations to quickly decay away due to the lack of an SU(2) symmetry for $H(t)$.

**Results** – In the following we investigate this, initializing the system in the ground state of $H(0)$ and time-evolving it under $H(t)$. We quantify the correlations in the $\eta$ symmetry sector using the particle-hole function $\langle \eta_i^+ \eta_j^- \rangle(t)$ which describes the mobility of a doublon between sites $i$ and $j$ at time $t$. We also introduce the doublon order parameter

$$D_\delta(t) = \frac{1}{N} \sum_{|i-j| \geq \delta} |\langle \eta_i^+ \eta_j^- \rangle(t)|,$$

where $N$ is a constant such that $D_\delta(t)$ is the average of the particle-hole function for distances greater than $\delta-1$.

In Fig. 2 we drive the system with a long, large-amplitude pulse for different values of $\tau'$. We observe that for $\tau' \neq 0$, $\langle \eta^+ \eta^- \rangle$ is not conserved as expected. The plots in Fig. 2, however, reveal that there is a critical value of $\tau'$ where the behavior of the system in the particle-hole channel changes significantly under driving. For $\tau' < \tau'_c \approx 0.69\bar{\tau}$ uniform, doublon order forms on transient time-scales and follows closely the $\tau' = 0$ evolution, despite the absence of the requisite symmetry. Meanwhile, for $\tau' > \tau'_c$ the system’s response in the particle-hole sector is much less ordered and the corresponding off-diagonal correlations quickly decay away. This distinct change in the system’s behaviour is underpinned by the action of the vertical hopping term $H_V$.

In Figs. 2b-c we see that for $\tau' < \tau'_c$ this term effectively acts like an annihilation operator which shuts down the particle-hole excitation pathway, preventing $\langle \eta^+ \eta^- \rangle$ from changing significantly and inducing long-range order amongst the available particle-hole correlations. As $\tau'$ increases above $\tau'_c$ this is no longer the case and the rate of change of $\langle \eta^+ \eta^- \rangle$ jumps by over an order of magnitude due to the creation of incommensurate particle-hole excitations which prevent robust order from being established in this sector.

We now probe the origin of these two distinct phases, calculating the properties of the ground state of the system which we drove out of equilibrium. In Fig. 3 we observe a rich phase diagram for the ground state of $H(0)$ in terms of $\langle \eta^+ \eta^- \rangle$ and $\langle S^+ S^- \rangle$. We also provide plots of the two-point correlations for states within these diagrams, alongside a finite-size scaling analysis (FSA) which indicates the phases we observe persist in the thermodynamic limit [39].

Within region I of Fig. 3a the ground state of the system resides in the lowest eigenspace of $\langle \eta^+ \eta^- \rangle$. Here, the system displays the properties of a spin-wave condensate through the large value of $\langle S^+ S^- \rangle$ underpinned by long-range spin-exchange order and a sharp 0 momentum peak in the corresponding structure factor. There are, however, two additional peaks of opposite momenta which correspond to interference in the condensate order due to further correlations between the central and outer sites of the lattice. This Spin-Wave Condensate (SWC) arises from the the irregular geometry of the lattice and is not possible in hypercubic realisations of the half-filled Hubbard model, where the ground state always has $\langle S^+ S^- \rangle = 0$.

As $\tau'$ increases, the value of the condensate order parameter $\langle S^+ S^- \rangle$ jumps discontinuously and the system undergoes a first-order phase transition into region II. In this phase, some of the vertically-bonded sites localise
and form singlets separate from the rest of the system, in which only small signatures of the condensate order observed in the previous phase remain. For even higher \( \tau' \) the system undergoes another first order phase transition into region III. Here, the vertical hopping is sufficiently large to create a spin-dimerized phase where all the vertically-bonded sites form singlets decoupled from the central sites.

For finite-size systems the I - II transition occurs along the left-most red dotted line in Fig. 3, where the condensate order parameter \( \langle S^+ S^- \rangle \) first jumps discontinuously. This is consistent with the critical change in non-equilibrium behaviour observed for \( \tau' \approx 0.69\bar{\tau} \) in Fig. 2. Our FSA indicates, however, that in the thermodynamic limit this transition, which is of first-order, occurs along the black-dotted line instead. This is because, as system size increases, the properties of the system in the light-blue region in Fig. 3b converge to those of phase I. We thus anticipate that the critical change in the non-equilibrium dynamics that we observed in Fig. 2 will occur at the higher value of \( \tau'_c \approx 0.86\bar{\tau} \) when \( L \to \infty \).

We understand this critical change in the non-equilibrium dynamics through the action of the vertical hopping term \( H_V \) in the different phases. In region I \( H_V \) acts as an annihilation operator, leading to the approximate conservation of \( \langle \eta^+ \eta^- \rangle \) and the formation of doublon-holon order. This action can be understood from the spin-wave nature of the ground state and that \( H_V \) only acts in the sub-lattice containing the outer sites of the system (marked in blue in Fig. 1). In this sub-lattice the spin-exchange correlations are large, positive and completely uniform with distance and so the two-site reduced density matrix (RDM) will be dominated by terms such as \( (\langle \uparrow \downarrow \rangle + \langle \downarrow \uparrow \rangle)(\langle \uparrow \downarrow \rangle + \langle \downarrow \uparrow \rangle) \); which are annihilated by a Hubbard hopping operator. Moreover, on short timescales the driving acts mainly to modify the longer-range correlations in the system, transiently preserving the form of the two-site RDM on neighbouring sites and thus the action of \( H_V \) as an annihilation operator. Meanwhile, in phases II and III, the condensate order disappears and the vertically bonded sites begin to form singlets. A hopping term will map a singlet onto \( |\eta^+ \rangle \langle \eta^-| \) as it gains energy [38].

In Figure 2 we drove the system with a long, large amplitude pulse, demonstrating the formation of stable doublon order for \( \tau' < \tau'_c \). In Fig. 4 we consider a larger system and use a shorter-lived, smaller amplitude pulse to drive the system out of equilibrium for \( \tau' < \tau'_c \) showing that the annihilative action of \( H_V \) still dictates the dynamics of the system. We focus on the role of the driving frequency, plotting the long-range order and absorbed energy as a function of the ‘bare’ frequency \( \omega = 2\bar{\tau} \) (the pulse form is \( \sin^2(\Omega t) \)) in Figs. 4a-b. These quantities both display doubly peaked profiles, with the peaks in the doublon order coinciding with those of the absorbed energy. This is indicative of heating-induced order, with the system relaxing to an ordered state due to the approximate conservation of \( \langle \eta^+ \eta^- \rangle \) as it gains energy [38].

We further illustrate this by showing the explicit evo-
volution of the particle-hole correlations for two different frequencies in Figs. 4c-d. There is a slower induction of order at the higher frequency, with the system also absorbing less energy from the driving field. Despite the finite value of τ′ we see the system is transiently relaxing towards a state with amplified, uniform off-diagonal correlations.

Interestingly, in Figs. 4a-b, for ω ≈ 2U the system absorbs the most energy and yet less long-range doublon order is induced compared to the first peak. This first peak is broad and shifted from ω = U, which is consistent with the pulse causing a number of excitations which all evolve differently and are necessary for the successful re-arrangement of the particle-hole degrees of freedom. The second peak is of a sharp, non-dispersive nature, containing only a small number of excitations which remain localised during the time evolution. Here, the time dynamics has become diabatic: the driving frequency is much larger than the localisation energy of the states involved in the process. This means that the system remains close to its original state with amplified, uniform particle-hole correlations.

Conclusion – We have studied the dynamics of the anisotropic driven two-rung triangular Hubbard model, showing how the rich ground state properties interact with the driving to create a phase which symmetry arguments fail to predict. In this phase, particle-hole excitations are prevented, causing the system to relax towards a state with amplified, uniform, particle-hole correlations.

The choice of a triangular Hubbard model was partly motivated by the role it has played in the modelling of the κ−(BEDT−TTF)2X compounds. The rich dynamical behaviour which occurs under driving may therefore be observable in these materials. Along these lines, the Hamiltonian in Eq. (1) was proposed as a model for a recent experiment optically exciting the vibrational modes of κ−(BEDT−TTF)2Cu[N(CN)2]Br [11]. The manifestation of particle-hole order we have witnessed here provides a potential explanation for the observed onset of light-induced superconductivity in this experiment. The experimental parameters are consistent with the system being driven close to ω = U from within the SWC phase and, more specifically, the Hamiltonian parameters and driving terms used in Fig. 4c were based on frozen-phonon simulations which determined the electronic properties of the photo-excited κ−(BEDT−TTF)2Cu[N(CN)2]Br molecules in Ref. [11].

More generally, the two-rung triangular Hubbard model allowed us to study the dynamics of a non-equilibrium, geometrically frustrated lattice structure. We anticipate that other systems which possess geometries characterised by frustration, inhomogeneous co-ordination numbers and anisotropic hopping terms - such as Kagomé lattices [44], optical quasi-crystalline structures [45], and doped cuprates [46] - will display similarly rich non-equilibrium physics.
