Introduction. Fertility preservation is an important aspect of quality of life in oncological patients, and in men is achieved by semen cryopreservation prior to treatment. Results of in vitro fertilization (IVF) procedures in healthy infertile couples are comparable, regardless of whether fresh or cryopreserved semen is used, but are scarce in male oncological patients.

Patients and methods. We performed a retrospective analysis of IVF/intracytoplasmic sperm injection (IVF/ICSI) procedures in infertile couples where men had been treated for cancer in the past. We additionally compared the results of IVF/ICSI procedures with respect to the type of semen used (fresh, cryopreserved).

Results. We compared the success rates of 214 IVF/ICSI cycles performed in the years 2004–2018. Pregnancy (30.0% vs. 21.4%; p = 0.12) and live-birth rates (22.3% vs. 17.9%; p = 0.43) per oocyte aspiration were similar between the groups in fresh cycles; however embryo utilization (48.9% vs. 40.0%; p = 0.006) and embryo cryopreservation rates (17.3% vs. 12.7%; p = 0.048) were significantly higher in the cryopreserved semen group. The cumulative pregnancy rate (60.6% vs. 37.7%; p = 0.012) was significantly higher, and the live-birth rate (45.1% vs. 34.0%; p = 0.21) non-significantly higher, in the cryopreserved semen group.

Conclusions. The success of IVF/ICSI procedures in couples where the male partner was treated for cancer in the past are the same in terms of pregnancies and live-births in fresh cycles regardless of the type of semen used. However, embryo utilization and embryo cryopreservation rates are significantly higher when cryopreserved semen is used, leading to a significantly higher cumulative number of couples who achieved at least one pregnancy.

Key words: assisted reproduction techniques; infertility; fertility preservation; sperm cryopreservation; pregnancy
azoospermia in adulthood when used for treatment prior to puberty; while other agents cause permanent or prolonged azoospermia only when applied in combination with other gonadotoxic agents (e.g. busulfan).\(^6\) Despite the fact that spermatogenesis can be reinstated after prolonged azoospermia and semen quality can be reduced\(^ {7,8} \), it doesn’t seem that intensified chemotherapy is the most important predictor for reducing fertility.\(^9\) It is therefore crucial that we explain the possible negative impact of oncological treatment on fertility, and offer the possibility of fertility preservation to male cancer patients prior to treatment.\(^ {10} \) Data in literature show that semen cryopreservation before the start of oncological treatment is a highly successful method for male fertility preservation.\(^ {11,12} \) This method can be used from puberty onwards. It has been shown that the success rate of in vitro fertilization (IVF) procedures in healthy men is comparable when fresh or cryopreserved semen is used.\(^ {13,14} \) Before puberty, only testicular tissue can be cryopreserved for later re-transplantation or in vitro manipulation after the end of treatment.\(^ {15} \) This procedure, however, is still experimental and has only been successfully used in animal models\(^ {16,17} \) and monkeys.\(^ {18} \)

The aim of the present study was to retrospectively analyze the success rates of IVF procedures that were performed with the semen of men who had been treated for cancer in the past. We determined whether there are differences in IVF/intracytoplasmic sperm injection (IVF/ICSI) success rates when fresh or cryopreserved semen is used.

**Patients and methods**

We performed a retrospective analysis of IVF/ICSI cycles in couples where the male partner had previously been treated for cancer. All consecutive cycles performed at our IVF center at the University Medical Centre in Ljubljana, in the period between January 2004 and December 2018, were included. First, we analyzed all cycles together, regardless of whether fresh or frozen semen was used for oocyte fertilization. We then divided the couples into two groups: one group in which cryopreserved semen was used for oocyte fertilization, and one group where fresh semen, obtained on the day of oocyte aspiration, was used. In all cases included in this retrospective study, the semen was cryopreserved before oncological treatment. Cryopreserved semen was used for IVF/ICSI in all azoospermic and aspermic patients. Fresh semen was used when the semen was of proper quality, so that high fertilization rates were expected. The decision on which sperm to use was made for each patient/sperm sample individually. If fertilization rates in cycles using fresh semen were low, frozen thawed semen was used in the next IVF/ICSI cycle. Similarly, if the development of embryos was poor in the previous cycle, we changed the type of semen to be used for the next IVF/ICSI procedure, where possible. Fresh semen was also used in patients where semen was not cryopreserved prior to oncological treatment.

In the majority of cases, embryo transfer was performed on day 5. However, in cases where there were only 1 or 2 embryos available for ET, or there was poor embryo development until day 5 in the previous cycle, embryos were transferred on day 3. In cases of poor embryo development, the rest of the embryos were cultured until day 5/6, and cryopreserved if developed to blastocysts of appropriate quality, according to Gardner et al.\(^ {19} \) The same criteria for the cryopreservation of supernumerary embryos were considered when all embryos were cultured until day 5/6.

To determine the differences between the groups, data were analyzed by using Pearson’s chi-square test, Fisher’s exact test and a Student’s t-test. A p value of less than 0.05 was considered as statistically significant.

The study did not have to be notified in the Ethics Committee according to Slovene law, as it was a register-based study where all the participants signed individual personal approval and permission before starting the treatment (Personal Data Protection Act, Official Gazette of the Republic of Slovenia No 94/07, 2004). Additionally, by Slovenian law, the healthcare providers are obligated to collect data about assisted reproduction procedures and follow the success rates (Healthcare Databases Act, Official Gazette of the Republic of Slovenia No 65/00, 2000; No 47/15, 2015; 31/18, 2018).

**Results**

We retrospectively analyzed the outcome of IVF/ICSI cycles where cryopreserved or fresh semen from male oncological patients was used for oocyte fertilization. Table 1 presents types of cancer, and the number of cases for each cancer type in the cryopreserved and fresh semen groups. There were 214 such IVF/ICSI cycles performed in 115 couples between January 2004 and December 2018. This represents 1.5% of all cycles performed during this
period. The mean female age was 31.9 ± 4.6 years. Altogether, 2,102 oocytes were retrieved (9.8 ± 5.8 per cycle). After fertilization (the results are for conventional IVF and ICSI together), 1,007 oocytes (47.9%) were fertilized, 363 (17.3%) were immature, 262 (12.5%) degenerated and 26 (1.2%) were incorrectly fertilized (polyploidies). Nine hundred and sixty-three fertilized oocytes (95.6%) developed into embryos, resulting in 4.5 ± 3.6 embryos per cycle. On the third day after oocyte aspiration, 63 (6.5%) of the embryos were transferred to the uterus, and the remaining embryos (900; 93.5%) were cultured until the fifth or sixth day of development. Of these embryos, 289 (32.1%) developed to blastocysts, and at least one blastocyst was obtained in 121 IVF/ICSI cycles (56.5%). Altogether, fresh embryo transfer (ET) was performed in 176 cycles; in 32 cycles (15.0%) there were no embryos of appropriate quality for transfer. Cryopreservation of all embryos was conducted in 6 cycles. Supernumerary embryos were cryopreserved (148; 15.4%) and cryopreservation was performed in 55 cycles (25.7%). Embryo utilization rate (the number of transferred embryos plus the number of cryopreserved) was 45.2%. Pregnancy rate per ET (with mean number of transferred embryos 1.6 ± 0.5) was 32.4% and 26.6% per oocyte aspiration. Miscarriage occurred in 12 pregnancies (21.1%). There were 44 deliveries

MII = metaphase II
Due to the nature of the oncological disease and its treatment, it is sometimes necessary to use the semen that has been cryopreserved prior to the start of the treatment in IVF/ICSI procedures. Therefore, we further analyzed whether there was a difference in the outcome of IVF/ICSI cycles, depending on whether fresh or cryopreserved semen was used. We summarized the types of cancer in male patients and the number of cases in Table 1, while the baseline characteristics of analyzed IVF/ICSI cycles are presented in Table 2. In the analyzed period, cryopreserved semen was used in 130 IVF/ICSI cycles, and fresh semen, obtained on the day of oocytes aspiration, was used in 84 IVF/ICSI cycles. Detailed results of these procedures are shown in Tables 3 and 4. Briefly, the cryopreserved semen and fresh semen groups were comparable for mean female’s age (31.7 ± 4.8 vs. 32.3 ± 4.3), mean number of oocytes retrieved per aspiration (9.8 ± 5.2 vs. 9.9 ± 6.7), fertilization rate per retrieved cumulus-oocyte complexes (46.3% vs. 50.4%), and mean number of embryos obtained per cycle (4.3 ± 3.4 vs. 4.8 ± 3.8). There was a significant difference in some causes of female infertility. Briefly, significantly more women had an endocrinological cause of infertility, and a significantly higher number of couples did not have any female’s cause of infertility in the cryopreserved semen group (Table 2). In the fresh semen group, a significantly higher number of women had more than one cause of infertility. In the cryopreserved semen group, a statistically significant higher rate of cryopreserved embryos (17.3% vs. 12.7%; p = 0.048) and a higher embryo utilization rate (48.9% vs. 40.0%; p = 0.006) were observed. Furthermore, ICSI was performed more often (93.8% vs. 84.5%; p = 0.025) in the cryopreserved semen group. ICSI was performed only in cases of impaired semen quality, (oligo-, astheno-, or teratozoospermia, or a combination of these conditions).

In terms of the clinical outcomes of IVF/ICSI cycles, there were no differences in pregnancy rate per ET (35.8% vs. 26.9%), live birth rate per fresh ET (26.6% vs. 22.4%) and miscarriage rate per pregnancy (25.6% vs. 11.1%) between the cryopreserved and fresh semen groups. As presented in Table 4, the proportion of day 3 ETs was similar between the analyzed groups. However, when we analyzed cumulative pregnancy rate per couple (fresh and frozen-thawed cycles together), the results showed that at least one pregnancy was achieved in 60.6%
of couples in the cryopreserved semen group, and in 37.7% of couples in the fresh semen group. The difference was statistically significant (p = 0.012). Despite this difference, the proportion of couples achieving at least one birth was similar on a cumulative level, with 45.1% in the cryopreserved group and 34.0% in the fresh semen group (p = 0.21).

There were 9 couples who underwent 33 cycles (16 cycles with cryopreserved semen and 17 cycles with fresh semen) and used both cryopreserved and fresh semen for the IVF/ICSI procedure. Four couples started the treatment with cryopreserved semen, five with fresh semen, and in 7 of these couples, the treatment led to live birth. One couple had two children, the first one conceived with cryopreserved semen, and second one with fresh semen.

The mean duration of cryopreservation of semen was 6.6 ± 4.4 years (minimum 1 year and maximum 19 years), and the mean semen volume per sample prior to cryopreservation was 3.1 ± 1.5 ml. The mean sperm concentration was 31.2 ± 30.7 million/ml, mean sperm motility 34.7 ± 10.3%, and the proportion of morphologically normal spermatozoa was 16.3 ± 14.3%. The mean number of cryopreserved straws per cryopreservation procedure was 8.1 ± 3.8; however, some patients underwent more than just one cryopreservation procedure, and the mean number of cryopreserved straws per patient was 11.2 ± 5.6. Until now, 40.0% of these samples have been used for IVF/ICSI procedures, and 14.1% of patients included in this analysis have used all of their cryopreserved semen. After the thawing of the samples, and before using them for the IVF/ICSI procedure, the mean sperm motility was 30.9 ± 19.9%, the proportion of morphologically normal spermatozoa was 20.1 ± 16.5%, and the mean sperm concentration was 18.8 ± 22.0 million/ml. This concentration is lower than in fresh samples, but this is to be expected because sperm samples are diluted in a 1:1 ratio with freezing solution before cryopreservation. In the group of patients where fresh semen was used, the mean sperm concentration was 34.7 ± 43.7 million/ml, mean sperm motility 50.0 ± 23.2%, and the proportion of morphologically normal spermatozoa was 16.2 ± 13.4%.

**Discussion**

In the present study, we performed a retrospective analysis of 214 IVF/ICSI procedures where fresh or cryopreserved semen of men, who were treated for cancer in the past, was used. We found that the success of the IVF/ICSI procedures, in terms of pregnancies and live-births after fresh embryo transfer, was the same regardless of the type of semen used. However, embryo utilization and cryopreservation rates were significantly higher when cryopreserved semen was used.
sperm was used, which led to a significantly higher cumulative number of couples who achieved at least one pregnancy. Despite this, the difference in cumulative number of live-births was not statistically significant. One reason for this could be in the non-significant higher number of miscarriages in the cryopreserved semen group.

Altogether, success rates of IVF/ICSI procedures in couples where men were treated for cancer in the past were comparable with success rates of IVF/ICSI procedures in the general population of infertile couples treated in our clinic, and also on a European level. Analyses of all IVF/ICSI cycles (combined data for cryopreserved and fresh semen and for IVF and ICSI) have shown that pregnancy rate per oocyte aspiration was 26.6%, which is similar to the pregnancy rate of infertile patients treated in our center in the same time period (2004–2018), 25.5% respectively, and the latest pregnancy rate reported for the general population in the European IVF Monitoring (EIM) data from 2016.20 EIM collects data on the performance of IVF procedures in European Union Member States (https://www.eshre.eu/Data-collection-and-research/Consortia/EIM). According to EIM data, in 2016, the proportion of pregnancy rate per oocyte aspiration was 28.0% for classical IVF and 25.0% for ICSI procedures.20

If we compare the remaining results (oocyte fertilization, embryo development) with which we evaluate the success of IVF/ICSI procedures, with criteria that determine the recommended minimum values23, we can see that not all of them reach these values. The desired proportion of fertilized oocytes according to these criteria is 65% for ICSI and 60% for classical IVF. In the present analysis, where we did not separate the data according to the type of IVF procedure used for oocyte fertilization, the proportion of fertilized oocytes was 47.9%, and when only ICSI was analyzed this proportion was 57.0%. This proportion is similar to the one reported in one of the very rare studies similar to ours, where 49% of oocytes were fertilized with classical IVF and 51% with ICSI.22 A similar thing is seen with the desired minimum proportion of embryos that develop to blastocysts. In our study, 32.1% of embryos cultured until day 5/6 developed to blastocysts, which is lower than the desirable 40%. It is important to note, however, that the minimum criteria are determined on the basis of the general population of “healthy” couples attending IVF. In our study, however, semen obtained from male oncological patients was used, and such semen has been shown to be of poorer quality.23,24 Therefore, the observed differences in our study are somewhat expected and most likely cannot be considered significant. In addition to the negative impact of the disease itself or oncological gonadotoxic treatment on the basic criteria of semen quality (number, motility, morphology), the negative impact of the disease is also reflected in increased sperm DNA fragmentation.25,26 Meta-analyses have shown that increased sperm DNA fragmentation negatively affects IVF/ICSI outcomes even in the healthy male population.27,28

Since a part of the IVF/ICSI procedures was performed with cryopreserved semen which was stored before oncological treatment, and a part of the procedures with fresh semen obtained on the day of oocyte aspiration, after oncological treatment was completed, we checked whether there were any differences in the success rates of IVF procedures according to the type of semen used. The literature shows that the success of IVF/ICSI procedures in healthy men is the same regardless of the type of semen (fresh, cryopreserved) used.30 However, relatively little data are available in men who have been treated for cancer. In part, the problem is that a relatively small proportion of men who cryopreserve semen before treatment also use it later. It is estimated that semen is used by 1.5% to 16.3% of men.11,22,29-35 Studies by van Casteren et al.11 Botchan et al.30 showed that the proportion of births (per oocyte aspiration) after the use of cryopreserved semen in cancer patients was 24% and 25%, respectively, which is similar to our results (22.3%). The study of van Casteren et al.11 states that in 20% of IVF/ICSI procedures no suitable embryo was obtained for transfer. This is more than in our study, where in 15.0% of procedures (cryopreserved and fresh semen) there were no embryos suitable for transfer. There are also studies that report higher (29% for IVF and 32% for ICSI)23 and much higher (50%)28 percentage of births per oocyte aspiration. The reason for such a large difference with our results may be in the higher average number of embryos transferred per transfer. At our department, a maximum of two embryos are transferred to the uterus at the same time. In the study of Hourvitz et al.28, the average number of embryos transferred to the uterus was 3.0 ± 1.1, which is significantly more than in our study (1.6 ± 0.5).

Interestingly, as mentioned above, our data have shown that in the group of couples where cryopreserved semen was used, embryo utilization and cryopreservation rates were significantly higher compared to couples where fresh semen was used. This finding implies that semen qual-
ity deteriorates after the oncological treatment. Data of currently published studies, however, are conflicting. Trottmann et al. stated that semen quality deteriorated drastically after oncological treatment. Weibring et al. reported similar observations, but further noted that semen quality improves 12 months after the end of treatment. Di Bisceglie et al. also found that semen quality starts to improve 18 months after the end of treatment. In addition, there is evidence of an improvement of sperm DNA fragmentation after the end of some oncological treatments. Despite these data, it is highly recommended that semen is cryopreserved in all oncological patients before treatment, even in those undergoing low-risk gonadotoxic treatment. This way, semen of better quality can be chosen to perform IVF/ICSI, if needed.

In the present study, a significantly higher number of women in the cryopreserved semen group did not have any cause of infertility, and IVF was only needed due to the male factor. One would assume that this is the cause of the significantly higher embryo cryopreservation rates in the cryopreserved semen. However, analysis of 121,744 women undergoing their first IVF/ICSI cycles has shown that IVF/ICSI success rates are most significantly affected by female’s age and not by female’s cause of infertility. No significant difference in women’s age was found in the present study.

As this is a retrospective study, there are some limitations in our data. We included cycles from a long time period, and some changes in our work have been introduced into clinical practice since then. For instance, in 2004, long GnRH agonist protocol was mostly used for controlled ovarian hyperstimulation, and it has been mostly replaced with short GnRH antagonist protocol since 2010. There have also been some changes in embryo culture approach, and embryos have been cultured in lower oxygen concentration (5%) since 2008. Prior to 2008, they were cultured in an atmospheric concentration of oxygen (21%). Additionally, there have been a few changes of manufacturers and types of embryo culture media. Despite these limitations, this shouldn’t impair the conclusions drawn from our results, as the described changes were applied for all couples (cryopreserved and fresh semen groups).

Conclusions

Semen cryopreservation before the start of oncological treatment is a widely accepted and successful method to maintain the fertility of men with cancer, as oncological treatment can negatively affect spermatogenesis. The results of our retrospective study show that the results of IVF/ICSI procedures in terms of pregnancies and live-birth rates after fresh embryo transfer are comparable regardless of whether we use fresh or cryopreserved semen from male cancer patients. Additionally, while the embryo utilization and embryo cryopreservation rates are higher if cryopreserved semen is used, this leads to a higher cumulative pregnancy rate and possibly to a higher cumulative birth rate. Overall results also show that the success rates of IVF/ICSI procedures where fresh or cryopreserved semen of male cancer patients was used are comparable with the results of IVF/ICSI procedures in the general population of infertile couples at European level, as well as with the population of couples treated at our clinic in the same time period.

Acknowledgments

The authors would like to thank all gynecologists, clinical embryologists, medical nurses and other staff at the Department of Human Reproduction, Division of Gynaecology, University Medical Centre Ljubljana, Slovenia, for their support.
